(Received 29 August 2016; published 31 October 2016)

Birhythmicity arises in several physical, biological, and chemical systems. Although many control schemes have been proposed for various forms of multistability, only a few exist for controlling birhythmicity. In this paper we investigate the control of birhythmic oscillation by introducing a self-feedback mechanism that incorporates the variable to be controlled and its canonical conjugate. Using a detailed analytical treatment, bifurcation analysis, and experimental demonstrations, we establish that the proposed technique is capable of eliminating birhythmicity and generates monorhythmic oscillation. Further, the detailed parameter space study reveals that, apart from monorhythmicity, the system shows a transition between birhythmicity and other dynamical forms of bistability. This study may have practical applications in controlling birhythmic behavior of several systems, in particular in biochemical and mechanical processes.

DOI: 10.1103/PhysRevE.94.042226

I. INTRODUCTION

Multistability is a common dynamical feature of many natural systems [1–3]. Although it appears in diverse forms, a very frequently occurred variant is bistability. There are three main manifestations of bistability: the coexistence of (i) two stable steady states, (ii) one stable limit cycle and one stable steady state, and (iii) two stable limit cycles. The third form of bistability, i.e., the coexistence of two stable limit cycles of different amplitude and frequency, generally separated by an unstable limit cycle, is called birhythmicity and oscillators showing this behavior are called birhythmic oscillators. Apart from two coexisting periodic limit cycles, birhythmicity may appear in a much more complex form, e.g., coexistence of two chaotic attractors [4,5]. Birhythmic oscillators are very common, particularly in physics (e.g., energy harvesting system; see Ref. [6] and references therein) biology (e.g., glycolytic oscillator and enzymatic reactions [1,2,7]), and chemistry [8]. Most of the biochemical oscillations that govern the organization of cell cycle, brain dynamics, or chemical oscillations are birhythmic; examples include birhythmicity in the p53-Mdm2 network, which is the key protein module that controls proliferation of abnormal cells in mammals [9,10], intracellular Ca2+ oscillations [2], oscillatory generation of cyclic adenosine monophosphate during the aggregation of the slime mold Dictyostelium discoideum [11], and circadian oscillations of the PER and TIM proteins in Drosophila [12].

In physical and engineering systems birhythmicity plays a negative role in limiting the efficiency of a certain application. Take the practical example of an energy harvesting system that converts wind-induced vibrational energy into electrical energy. This type of energy harvesting systems show birhythmicity [6], but for an efficient harvesting it is desirable that the system always resides in the large-amplitude limit cycle because that produces a significant mechanical deformation, which in turn results in a larger amount of harvested electric power. Further, the presence of birhythmicity makes a system vulnerable to noise: Depending upon the noise intensity, the system may end up in any of the two limit cycles, which results in an unpredictable system dynamics [3,13]. Therefore, monorhythmicity is of practical importance in most of the physical systems. On the other hand, in networks of neuronal oscillators the occurrence of birhythmicity is often desirable to generate and maintain different modes of oscillations that organize various biochemical processes in response to variations in their environment [8]. Therefore, identifying an efficient control technique that can tame birhythmicity to yield monorhythmic oscillation or can retain its character intact wherever needed is of importance.

Although several mechanisms are proposed for controlling bistability consisting of oscillation and a steady state [14] (for an elaborate recent review on the control of multistability see [3] and references therein), only a few exist to control birhythmicity. Ghosh et al. [15] reported an effective control mechanism of birhythmic behavior in a modified van der Pol system by using a variant of the Pyragas technique of time delay control [16] and they showed that, depending upon the time delay, one can induce monorhythmic oscillation out of birhythmicity. However, due to the presence of time delay, the system becomes infinite dimensional and thus a detailed bifurcation analysis for a wide parameter space is difficult and was not reported there. Further, the authors of [15] established that their technique can suppress the effective birhythmic zone but cannot eliminate it completely for all possible sets of nonlinear damping parameter values. In this context, another interesting control technique has been reported recently by Sevilla-Escoboza et al. [17], where the authors demonstrated that multistable systems with coexisting periodic or chaotic attractors can be converted into a monostable one by applying an external harmonic modulation and a positive feedback to a proper accessible system parameter.
III. CONTROL OF BIRHYTHMICITY THROUGH CONJUGATE SELF-FEEDBACK: THEORY

Next we introduce a conjugate self-feedback term \( d(\dot{x} - x) \) in Eq. (1),
\[
\ddot{x} - \mu(1 - x^2 + \alpha x^4 - \beta x^6) \dot{x} + x + d(\dot{x} - x) = 0, \tag{3}
\]
which contains the variable of our interest \( x \) and its canonical conjugate \( \dot{x} \); here \( d \) controls the strength of the self-feedback. Further, a close inspection reveals that the self-feedback mechanism effectively controls the damping of the system through the \( \dot{x} \) variable and the effective frequency through the \( x \) variable. However, understanding of their collective effect on the dynamics needs a detailed analysis, which we will address next.

To unravel the underlying dynamics of the controlled system we use the harmonic decomposition method. Let us assume that the approximate solution of (3) is given by
\[
x(t) = A \cos \omega t, \tag{4}
\]
with \( A \) being the amplitude and \( \omega \) the frequency of the oscillator with feedback. Substituting this in (3) yields the expression
\[
(-\omega^2 - d + 1)A \cos \omega t = -\mu A \left(1 - \frac{1}{4} A^2 + \frac{\alpha}{8} A^4 - \frac{5\beta}{64} A^6\right) \sin \omega t + d A \sin \omega t
\]
\[
+ \mu A \left(1 - \frac{3\alpha}{16} A^4 + \frac{9\beta}{64} A^6\right) \sin \omega t
\]
\[
- \mu A \left(\frac{\alpha}{16} A^4 - \frac{5\beta}{64} A^6\right) \sin 5\omega t + A^2 \beta \mu A \sin 7\omega t. \tag{5}
\]
Equation (5) can be reduced to
\[
(-\omega^2 - d + 1)A \cos \omega t = -\mu A \left(1 - \frac{1}{4} A^2 + \frac{\alpha}{8} A^4 - \frac{5\beta}{64} A^6\right) \sin \omega t + d A \sin \omega t + \mathcal{H}, \tag{6}
\]
where \( \mathcal{H} \) denotes higher harmonic terms. Equation (6) suggests the following frequency and amplitude equations, respectively:
\[
\omega^2 + d - 1 = 0 \tag{7}
\]
and
\[
\mu \left(1 - \frac{1}{4} A^2 + \frac{\alpha}{8} A^4 - \frac{5\beta}{64} A^6\right) - d = 0. \tag{8}
\]
It is interesting to note that Eq. (8) is equivalent to Eq. (2) when \( d = 0 \), i.e., in the absence of any feedback. Also, it may be noted that the amplitude of the system depends on \( \mu \) when \( d \neq 0 \), contrary to Eq. (2). The frequency in the harmonic limit corresponds to \( \omega = 1 \). Further, Eq. (7) imposes an upper limit on the strength of the feedback, namely, \( d \leq 1 \); otherwise the frequency becomes imaginary, which is nonphysical. The three roots (actually six roots, with \( \pm A_i \), \( i = 1, 2 \)) correspond to the amplitudes of three limit cycles (two stable, one unstable). We can get a hint of the amplitude of the limit cycles and test the stability using the energy balance method as suggested.
in Ref. [15]. From Eq. (3) one can infer that, for \( \mu = 0 \) and \( d = 0 \), the harmonic solution may be given by [23]

\[
x(t) = A \cos(t + \phi),
\]

where \( \phi \) is the initial phase, preferably \( \phi = 0 \) for convenience. The phase plane of this solution is a circle with period \( T = 2\pi \).

In the presence of self-feedback we can approximate

\[
x(t) \approx A \cos t.
\]

Now the change in energy \( \Delta E \) in one period \( 0 \leq t \leq T \), where \( T = 2\pi \), may be found if one considers the terms \( \mu(1 - x^2 + \alpha x^4 - \beta x^6) - d(\dot{x} - x) \) as the external forcing term as

\[
\Delta E = E(T) - E(0) = \int_{0}^{T} [\mu(1 - x^2 + \alpha x^4 - \beta x^6) - d(\dot{x} - x)] dt.
\]

For a periodic solution (limit cycle), the change in energy must be zero, i.e., \( \Delta E = 0 \). Hence the above integration along with the condition of Eq. (10) yields

\[
f(A^2) = \mu \left( 1 - \frac{1}{4} A^2 + \frac{\alpha}{8} A^4 - \frac{5\beta}{64} A^6 \right) - d = 0.
\]

Again, we see that Eq. (12) is identical to Eq. (8). In the absence of the coupling Eq. (12) reduces to Eq. (2). The saddle-node bifurcation may be controlled by changing the value of \( d \).

Equation (12) may be solved to have a number of positive roots, which determines the number of limit cycles (LCs). One can determine the stability of the limit cycle by the slope of the curve of Eq. (12) at the zero crossing points. The negative slope determines the stable limit cycle. Thus, we can write

\[
\left. \frac{d\Delta E(A)}{dA} \right|_{\text{limit cycle}} < 0 \tag{13}
\]

as the condition for a stable limit cycle.

Now let us discuss how to determine the presence of limit cycles and their stability from the above analytical results. The amplitude equation (12) may be solved by graphical method. The solutions are those for which the function \( f(A^2) \) crosses the horizontal zero line. We consider the parameter set of \( \mu = 0.1, \alpha = 0.114, \) and \( \beta = 0.003 \) for which (3) exhibits birhythmicity in the absence of self-feedback; next we vary the coupling strength \( d \) to get different solutions. The number of limit cycles is determined by the number of solutions of the amplitude equation. The number provides information about the steady-state solution (i.e., no solution) and the existence of a single limit cycle (monorhythmicity) or three limit cycles (birhythmicity, where one of the LCs is unstable). From Fig. 2 we find that for \( d = 0.2 \) there is no zero crossing of the curve, i.e., there is no LC and the system is in a steady state. As we decrease \( d \), the \( f(A^2) \) curve crosses the horizontal zero line from below and gives rise to a stable LC. This is shown for \( d = 0.05 \) with a solid gray (green) line; here the system has only one stable LC of small amplitude. A further decrease in \( d \) brings it to the birhythmic regime, where the \( f(A^2) \) curve crosses the horizontal zero line at three different values of \( A^2 \), indicating three LCs (shown for \( d = -0.02 \)). The stability of the three LCs is determined by Eq. (13), which suggests that the middle zero point of the curve in Fig. 2 represents the unstable LC. A further increase in \( d \) brings the system to a monorhythmic region with a large LC. The case of a large single LC for \( d = -0.1 \) is shown in the upper solid dark (red) line.

The original birhythmic van der Pol oscillator given by (1) exhibits only a global SNLC type of bifurcation. However, due to the presence of the feedback term in the controlled case [i.e., Eq. (3)], Eq. (2) is modified to Eq. (8) and thus the system additionally exhibits local bifurcation, namely, Hopf bifurcation. We derive the value of \( d \) for which Hopf bifurcation occurs from the eigenvalues of the Jacobian of Eq. (3) around the steady state \((x, \dot{x}) = (0, 0)\). The eigenvalues are given by

\[
\lambda_{1,2} = \frac{1}{2} [(\mu - d) \pm \sqrt{(d - \mu)^2 - 4(1 - d)}].
\]

Equation (14) gives the condition of Hopf bifurcation as

\[
d_{\text{HB}} = \mu,
\]

where \( d_{\text{HB}} \) is the value of \( d \) for which Hopf bifurcation occurs.

IV. NUMERICAL BIFURCATION ANALYSIS

In this section we investigate the possible bifurcation scenarios of the system using the continuation package XPPAUT. We explore the nature of the bifurcation with the variation of the feedback parameter \( d \) for different system parameters (e.g., \( \mu, \alpha, \) and \( \beta \)).

A. Dynamics in \( d-\mu \) space

The bifurcation structure in the \( d-\mu \) space is computed and shown in Fig. 3(a). The values of \( \alpha = 0.114 \) and \( \beta = 0.003 \) are kept in the birhythmic zone of the uncontrolled system (cf. Fig. 1). We find that the two-parameter space is divided by global bifurcations, namely, SNLC, and a local bifurcation, namely, the supercritical Hopf bifurcation (HB). In between two SNLC curves birhythmic behavior exists [purple (gray) zone]: In this zone three LCs exist, of which two are stable (one with smaller amplitude and the other with larger amplitude) and one is unstable. The transition from birhythmic
to monorhythmic dynamics [indicated by the green (light gray) zone] is governed by these SNLC curves, whereas the HB curve governs the transition between a single stable limit cycle and a stable steady state [blue (dark) zone]; note that the occurrence of the Hopf bifurcation agrees with our analytically predicted value of $d$ in (15).

For a clearer understanding of the bifurcation scenario we take an exemplary value $\mu = 0.1$ and vary the feedback term $d$ [along the dashed (yellow) horizontal line in Fig. 3(a)]. The one-parameter bifurcation diagram corresponding to this variation is shown in Fig. 3(b). In the absence of the self-feedback, i.e., for $d = 0$, the system is in a birhythmic zone for any $\mu > 0$ (in the present parametric setup). If we increase $d$, for $d > d_L$, the system enters into the monorhythmic zone via SNLC bifurcation. Here we observe that the sole limit cycle in the system is the small-amplitude LC. This small LC loses its stability through an inverse Hopf bifurcation and creates a stable steady state. On the negative side of $d$, for $d < -d_L$, we again have a monorhythmic region but with a large-amplitude limit cycle. Therefore, with a proper choice of the self-feedback strength $d$ one can induce monorhythmic oscillation of smaller ($d > d_L$) or larger ($d < -d_L$) amplitude. Interestingly, a hysteresis appears around $d = 0$ having a width of $\Delta d = (d_L - d_U)$ [light gray (purple) of Fig. 3(b)]. In this range of $d$ the system may end up showing a LC of large or small amplitude depending upon initial conditions. Also, the two LCs are separated by an unstable LC [shown as a dark (blue) line]. It is worth noting that the width of the hysteresis zone increases with increasing $\mu$.

Typical time series with the variation of $d$ are shown in Fig. 4 ($\mu = 0.1$, $\alpha = 0.114$, and $\beta = 0.003$). To detect the presence or absence of birhythmicity, we consider a large number of initial conditions of $(x, \dot{x})$. However, here we present the results for two different initial conditions only: one around the origin (targeting the small-amplitude LC) and the other far from the origin (targeting the large-amplitude LC). The red solid line indicates the oscillation corresponding to the initial condition $I_1 \equiv (x_0, \dot{x}_0) = (0.1, 0)$ and the black dotted line indicates the oscillation for the initial condition $I_2 \equiv (x_0, \dot{x}_0) = (7, 0)$. We start from a negative $d$ with $d < -d_U$. Figures 4(a) (time series plot) and 4(b) (phase plane plot) show the scenario for $d = -0.2$. Both initial conditions result in the large-amplitude LC, indicating monorhythmicity. Next we choose $-d_L < d < d_U$, i.e., the birhythmic region. Figures 4(c) and 4(d) show this scenario for $d = -0.02$. The blue trajectory in Fig. 4(d) indicates the unstable LC that separates the basin of attraction of two LCs, i.e., the small LC resulting from $I_1$ and the large LC resulting from $I_2$. Figures 4(e) and 4(f) show monorhythmic oscillation for $d = 0.05$ (i.e., $d > d_U$). Here all the initial conditions are for the smaller-amplitude LC. Finally, a further increase in $d$ results in a stable steady state [Figs. 4(g) and 4(h) for $d = 0.2$]. Therefore, with the variation of $d$ we can effectively control the birhythmic nature of the system and can induce a monorhythmic oscillation of preferred amplitude.
\[ \alpha = \text{the horizontal dashed yellow line of Fig. 5(a) (i.e., for } d_C \text{ the SNLC and HB curves intersect. In addition, } d \text{ shows the bifurcation scenario with the variation of } \beta \text{ of } \alpha \text{ and } \beta. \]

We find that one can indeed induce monorhythmicity for any set of nonlinear damping parameter space. Significantly, we observe that the time scale is much reduced, of the order of a few hours, e.g., birhythmic oscillation in the p53 system has two time scales of 6 and 10 h [26]. In this context, the experimental observation of birhythmicity was made by Decroly and Goldbeter [25] in a chemical system, namely, the parallel coupled bromate-chlorite-iodide system. In their experiment the time scale was of the order of a few minutes. On the other hand, in an electronic circuit possessing two distinct advantages: the presence of inherent noise and parameter fluctuation in a real system and also owing to the fact that in experiments one can record only one oscillation at a time [1]. The presence of inherent noise and parameter fluctuation in a real system and also owing to the fact that in experiments one can record only one oscillation at a time [1]. The parallel coupled bromate-chlorite-iodide system. In their experiment the time scale was of the order of a few minutes.

Finally, we summarize our results in the \( \alpha \)-\( \beta \) parameter space. For the uncontrolled system, i.e., \( d = 0 \), birhythmicity occurs in a broad zone of \( \alpha \)-\( \beta \) values as shown in Fig. 1(a). However, for \( d < d_C \) the birhythmic zone is completely eliminated and the only possible dynamics is essentially monorhythmic [Fig. 1(a) for \( d = -0.1 \)]. Therefore, our study reveals that a proper choice of the control parameter \( d \) can effectively eliminate birhythmicity to establish monorhythmic oscillation and at the same time its variation may give rise to transitions between several interesting dynamical states; by controlling \( d \) one can achieve any of these states in a deterministic way.

**V. Experiment**

Experimental observation of birhythmicity is subtle due to the presence of inherent noise and parameter fluctuation in a real system and also owing to the fact that in experiments one can record only one oscillation at a time [1]. The first experimental observation of birhythmicity was made by Decroly and Goldbeter [25] in a chemical system, namely, the parallel coupled bromate-chlorite-iodide system. In their experiment the time scale was of the order of a few minutes. In biological experimental setups the time scale is usually of the order of a few hours, e.g., birhythmic oscillation in the p53 system has two time scales of 6 and 10 h [26]. In this context, the experimental observation of birhythmic oscillation in an electronic circuit possesses two distinct advantages: First is that the time scale is much reduced, of the order of a few minutes.
integrators (A5 and A7) are charged with external voltages to have selected initial conditions, the capacitors (C) in the circuit get charged to the desired input voltages (±V1 and ±V2), which are taken and controlled from the computer through DAQ. Then the relays are turned off and the circuit operates in its normal state.

To demonstrate birhythmicity and verify the robustness of our proposed control scheme, we realize the system given by Eq. (3) in the electronic circuit. A detailed circuit diagram is shown in Fig. 7. Here M1–M4 are analog multiplier integrated circuits (AD633JN) and A1–A9 are operational amplifiers (TL074). The resulting circuit equation takes the form

\[
RC \frac{dW}{dt} = V, \quad R \frac{dV}{dt} = R_{\mu} \left[ V_a - V^2 \left( V_a - V^2 \left( V_a - R_\beta \right) \right) \right],
\]

with substitutions: \( t = \frac{1}{RC}, x = V, y = W, \frac{R_\beta}{R} = d, V_a = 1 \text{ V}, V_a = \alpha \text{ V}, \) and \( \frac{R_\beta}{R} = \beta \); with these Eqs. (16) are reduced to Eq. (3).

We consider the following values of the used circuit components throughout the experiment: \( R_\beta \approx 1 \text{ k} \Omega, R_d \approx 259.6 \text{ } \Omega, V_a \approx -1.119 \text{ V}, \) and \( V_a \approx 321.4 \text{ mV} \). The initial conditions are controlled through the data acquisition system (DAQ) in the LabVIEW environment [27] through a computer. To have selected initial conditions, the capacitors (C) in the integrators (A5 and A7) are charged with external voltages (±V1 and ±V2). These voltages are controlled by the DAQ. The voltages are connected to relays (S1 and S2) to be on for a particular time period. The on time of the relays are controlled by a microcontroller (Arduino Uno [28]), which is programmed to keep the relays on for a time interval of 5 s. During this time the capacitors of the integrators get charged to the desired input voltages (±V1 and ±V2), which are taken and controlled from the computer through DAQ. Then the relays are turned off and the circuit operates in its normal state.

The experimental time series and phase plane plots are shown in Fig. 8. To observe the large-amplitude single LC shown in Figs. 8(a) and 8(b) we add an inverter in the output terminal of A9 of Fig. 7 (not shown in the figure) and take \( R_d \approx 390 \text{ } \Omega \). Figures 8(c) and 8(d) show the scenario of birhythmicity for \( R_d \approx 0 \text{ } \Omega \). The presence of oscillations of two different amplitudes and frequencies confirms the occurrence of birhythmicity in the circuit. The increasing \( R_d \) brings the system to a monorhythmic one. The situation for \( R_d \approx 57.7 \text{ } \Omega \) is shown in Figs. 8(e) and 8(f). With a further increase in \( R_d \) the oscillation is quenched and the system rests in the stable steady state. Figures 8(g) and 8(h) show the case for \( R_d \approx 895 \text{ } \Omega \). Note the qualitative resemblance between the experimental scenarios and the numerical results of Fig. 4.

VI. CONCLUSION

In summary, we have proposed a scheme to control birhythmic behavior in nonlinear oscillators. Our control scheme incorporates a self-feedback term that is governed by the variable to be controlled and its canonical conjugate. We have considered a prototypical model that shows birhythmic oscillation and has relevance in modeling biochemical processes. Our study has revealed that a proper choice of the control parameter can effectively eliminate birhythmicity.
for any choice of nonlinear damping parameters and at the same time its variation may give rise to transitions between several interesting dynamical behaviors. Physical implementation of our control scheme is very much feasible, since feedback through conjugate variables is quite natural in many experimental setups [29]. We can realize the control scheme if we have access to at least one of the variables of interest; from that we can always generate its time derivative via real time signal processing. We believe that our study may have potential applications in controlling birhythmicity in several mechanical and biochemical processes as well as in other fields.
