15

16 **Abstract.** Although disruption of glucose homeostasis is a hallmark of ageing in humans and
17 laboratory model organisms, we have little information on the importance of this process in free-
18 living animals. Poor control of blood glucose levels leads to irreversible protein glycation. Hence,
19 levels of protein glycation are hypothesised to increase with age and to be associated with a decline
20 in survival. We tested these predictions by measuring blood glycated haemoglobin in 274 adult
21 collared flycatchers of known age and estimating individual probability of recapture in the following
22 two years. Results show a strong decrease in glycated haemoglobin from age one to five years and an
23 increase thereafter. Individuals with high levels of glycated haemoglobin had a lower probability of
24 recapture, even after controlling for effects of age and dispersal. Altogether, our findings suggest
25 that poor control of glucose homeostasis is associated with lower survival in this free-living bird
26 population, and that the selective disappearance of individuals with the highest glycation levels could
27 account for the counter-intuitive age-related decline in glycated haemoglobin in the early age
28 categories.

29

30 **1.Introduction**

31 Glucose is a major source of energy for cellular processes and its transport, storage and metabolism
32 are tightly regulated in vertebrates [1]. Low glycaemia results in stress and starvation, whereas high
33 glycaemia leads to cellular damage [2,3]. Glucose can indeed react spontaneously with proteins to
34 form advanced glycation end-products. This non-enzymatic glycation process, referred to as Maillard
35 reaction [3], impairs protein function. Advanced glycation end-products are often irreversible and
36 glycation could thus be responsible for the frequently observed link between disruption in glucose
37 homeostasis and ageing [3,4].

38 Because haemoglobin is the most abundant protein in red blood cells, haemoglobin glycation
39 is a standard marker of exposure to damaging levels of glucose in medical research [5]. In agreement
40 with the hypothesis that disruption of glucose homeostasis and ageing are closely related, glycated
41 haemoglobin in humans increased during the life course of individuals [6] and high levels of glycated
42 haemoglobin were associated with increased mortality [7]. Surprisingly few studies have investigated
43 age-related variation of glycated proteins in non-human vertebrates. They provide conflicting results,
44 showing an increase with age in some free-living and captive mammal and bird species, but a
45 decrease between **juvenile** and mid-age individuals in another free-living bird species [8,9]. Hence,
46 variation of glycated proteins in relation to age in free-living populations may be more complex than
47 initially thought.

48 Here, we described the age-related variation of glycated haemoglobin using cross-sectional
49 data from a free-living bird population. Because senescence in survival, reproduction and immunity is
50 only observed after five years in our study species [10,11], we expected an increase in glycated
51 haemoglobin in individuals above this age. However, age-related variation in haemoglobin glycation
52 at the population level can also be shaped by between-individual variation and changes in the
53 composition of the population with age, rather than to within-individual variation and thus ageing
54 per se [12]. We explored the individual-level processes shaping age-related variation of glycated
55 haemoglobin by testing whether glycated haemoglobin was associated with a proxy of individual

56 probability of survival.

57

58 **2. Material and methods**

59 The study was conducted in May-June 2009 to 2011 on a breeding population of collared flycatchers
60 (*Ficedula albicollis*) on the island of Gotland, Sweden (57°10'N, 18°20'E). Nest boxes were checked
61 regularly to monitor reproduction and parents were trapped in their nest box 6 to 12 days after the
62 onset of incubation for females and 5 to 13 days after hatching for males (i.e. during nestling
63 provisioning). Upon capture, adults were identified or ringed with aluminium rings, weighed,
64 measured (tarsus length) and blood sampled (100 to 130µl from the brachial vein in EDTA-coated
65 Microvettes; Sarstedt, Germany). In 2009, we sampled 274 adult birds of known age, from one to
66 eight years (table 1): 193 were ringed as nestlings and 81 were ringed as yearlings. Their subsequent
67 return rate, dispersal within the study area, and reproductive success were monitored in 2010 and
68 2011. Dispersal within the study area was defined as a change of breeding plot, either between birth
69 and the first breeding event or between two consecutive breeding events [13]. Breeding plots were
70 also separated into two categories: central plots and peripheral plots, because the probability of
71 dispersing outside of the study area is higher at the edge [14].

72 The fraction of glycated haemoglobin was measured using the Biocon Diagnostik© HbA1 kit
73 (Biocon Diagnostik, Germany), after minor adaptation of the manufacturer protocol to analyse small
74 samples. 5µl red blood cells were suspended in 150µl PBS, then 100µl of this suspension was mixed
75 with 500µl of the lysis reactant and centrifuged. To quantify total haemoglobin, 40µl supernatant
76 was diluted in 1000µl ultrapure water before reading the absorbance at 440 nm (A_{Hbtotal}). To quantify
77 glycated haemoglobin, 100µl supernatant was mixed with 1.2mL of cation-exchange resin, and then
78 separated by filtration. The absorbance was read at 440nm (A_{HbA1}). The absorbance ratio
79 ($A_{\text{HbA1}}/A_{\text{Hbtotal}}$) was standardized using the kit calibrator. Each sample was analysed in duplicate in a
80 first assay, then once in a second assay. The inter- and intra-assay CV were respectively 13.7% and
81 7.9% (N = 364 samples).

82 Levels of glycated haemoglobin were log-transformed before analysis using a linear model
83 with sex, body mass, tarsus length, and linear and quadratic age as explanatory variables. The return
84 rate (i.e. the probability to be caught again in 2010, or 2011 for individuals missed in 2010) was
85 analysed using binomial generalized linear models (GLMs). To check whether return rate was a
86 reliable proxy of survival, we investigated how glycated haemoglobin related to other sources of
87 non-detection, such as dispersal outside of the study area and early breeding failure. We tested
88 whether glycated haemoglobin was related to the probability of dispersal within the study area
89 between 2009 and 2010 and the probability of successfully fledging at least one offspring in 2010
90 with binomial GLMs, as well as the number of fledglings for successful nests with a linear model.
91 Return rate, dispersal within the study area and reproductive output were modelled as a function of
92 glycated haemoglobin, linear and quadratic age, sex, body mass and tarsus length, as well as the
93 position of the breeding plot for return rate and dispersal. For analyses of reproductive output, both
94 pair members were sampled for 8 breeding pairs and their reproductive data were thus not
95 independent; however, excluding these pairs did not qualitatively change our results. Because
96 females and males were sampled during two distinct stages (incubation and nestling rearing,
97 respectively), we tested for sex-specific patterns in each model (tables S1-S3). Dispersal and timing of
98 egg laying varied with age (tables S4-S5) and could relate to differences in resource use, and thus
99 glycated haemoglobin, during migration and settlement, but including laying date or dispersal status
100 between 2008 and 2009 as covariates did not alter our results (tables S4-S5). Analyses were based on
101 type-II F-tests using the function *Anova* of the R package *car* [15].

102

103 3. Results

104 The fraction of glycated haemoglobin varied between 0.73% and 3.72% (median = 1.15%, mean \pm SE
105 = 1.33 ± 0.47 %). The log-transformed fraction of glycated haemoglobin followed a quadratic
106 relationship with age, showing a strong significant decline between 1 and 5 years of age and a slight
107 but significant increase between 5 and 8 years of age (table 2a, figure 1). The return rate was 39.1%

108 on average (95% confidence interval: 33.2% – 45.1%), i.e. lower than annual survival in this
109 population estimated via capture-mark-recapture as 56.8% (95% confidence interval: 52.9% – 60.7%)
110 [16]. Only eight returning individuals out of 107 (7.5%) were caught again in 2011 but not in 2010.
111 Return rate decreased with increasing fraction of glycated haemoglobin (table 2b, figure 2). Return
112 rate was not explained by the position of the breeding plot within the study area (table 2b). The
113 probability of dispersal within the study area between 2009 and 2010, of successfully fledging at
114 least one offspring in 2010, as well as the number of offspring fledged for successful nests, were
115 independent of the fraction of glycated haemoglobin (table 2c, d and e). The variation in glycated
116 haemoglobin with age, as well as the effects of glycated haemoglobin on return rate, dispersal and
117 future reproduction, did not differ significantly between sexes (tables S1-S3).

118

119 **4. Discussion**

120 In agreement with the positive association between disruption of glucose homeostasis and mortality
121 in humans [7], breeding collared flycatchers with higher level of glycated haemoglobin were less
122 likely to be caught again in the two years following their sampling, independent of age. In natural
123 populations, a lower observed return rate might be due to higher early breeding failure and/or
124 higher dispersal out of the study area. We found no support for such alternative mechanisms
125 underlying the association between glycated haemoglobin and return rate. Indeed, levels of glycated
126 haemoglobin did not predict breeding failure (after the first capture of the parent) or dispersal within
127 the study area the following year. Return rate was also not biased by the position (i.e. periphery vs.
128 centre) of the breeding plot within the study area. Altogether, these findings provide strong evidence
129 that high levels of glycated haemoglobin are associated with increased mortality risk.

130 At the population level, we observed a counter-intuitive significant decrease in glycated
131 haemoglobin from one to five years of age and an expected increase thereafter (but with small
132 sample sizes). This decline at early age is possibly driven by the selective disappearance of individuals
133 with the highest glycation levels [12]. Demonstrating changes in the fraction of glycated haemoglobin

134 with age requires a longitudinal analysis using repeated sampling of the same individuals over their
135 lifetime. Nevertheless, senescence patterns in physiological markers were detected in small cross-
136 sectional datasets in this species ([11] and this study), likely because they measure individual
137 performance more accurately than binary (survival, breeding failure) or ordinal (fledglings number)
138 traits.

139 Interestingly, previous research in natural bird populations has reported positive
140 relationships between glycated haemoglobin and fitness-related traits such as nestling growth [17]
141 and adult reproductive success [18], suggesting that high levels of glycated haemoglobin could reflect
142 higher nutritional state. Our results however show that glycated haemoglobin is negatively
143 associated with a proxy of survival. Taken together, these results suggest that increased metabolic
144 demands through growth and reproduction translate into increased costs in terms of glycation and
145 subsequent mortality. Glycated haemoglobin could thus mediate life-history trade-offs.

146 Although senescence in free-living animals is now well demonstrated [19], we often lack
147 information on the factors associated with age-related mortality in nature [20]. This is however
148 essential to identify conserved mechanisms of senescence in the animal kingdom [20]. Our study
149 supports the idea that disruption of glucose homeostasis decreases survival and could contribute to
150 ageing in natural populations.

151

152 **Ethics statement.** Birds were caught, handled and ringed under a license from the Stockholm
153 Museum Ringing Center (license number 471) and blood samples were collected under a general
154 license from the Swedish Committee for Experiments on Animals for all experiments on the site
155 (license number C 108/7).

156 **Data accessibility.** Data are available from the Dryad Digital Repository:
157 <http://dx.doi.org/10.5061/dryad.87035>

158 **Authors' contributions.** CR, BD and PB designed the study; LC and BD performed the fieldwork; CR
159 and AS carried out the laboratory and statistical analyses; CR, BD and PB drafted the manuscript and

160 AS and LC revised it for significant intellectual content. All authors approved of the manuscript and
161 agree to be held accountable for its content.

162 **Competing interests statement**

163 The authors declare that they have no competing interests.

164 **Acknowledgements.** Many thanks to Lars Gustafsson and the landowners of Gotland for access to
165 the study sites, to Alice Terrier for her help in collecting samples, to numerous field assistants for
166 their help in monitoring the population, to Ryan Germain for proofreading, and to François Criscuolo
167 and two anonymous reviewers for helpful feedback on an earlier version of this manuscript.

168 **Funding statement.** This work was supported by the ANR (ANR-06-JCJC0082 to BD), the CNRS (PEPS
169 INEE and PICS France-Switzerland to BD), the French Ministère de l'Enseignement Supérieur et de la
170 Recherche (PhD fellowship to CR), the Région Rhône-Alpes (Explora'doc mobility grant to CR), the
171 University of Aberdeen (stipend to CR), the L'Oréal Foundation-UNESCO "For Women in Science"
172 program (fellowship to CR), the Rectors' Conference of the Swiss Universities (grant to CR and PB).

Age-related variation in glycosylated haemoglobin from 274 adult collared flycatchers
figure 1
916x416mm (72 x 72 DPI)

Probability of recapture in the two years following the measurement of glycated haemoglobin. The fitted solid line shows the probability of recapture estimated from a binomial GLM together with 95% confidence interval (dashed lines).
