Keywords; FTIR, quantification, Fischer Tropsch, alkyl species, Cobalt catalyst.

Abstract

In-situ FTIR spectroscopy was employed to investigate the location, chain length and quantity of hydrocarbon species adsorbed on supported-cobalt Fischer-Tropsch catalysts. The length of the hydrocarbon units observed was quantified using an appropriately determined absorption coefficient ratio. The individual amounts of CH₂ and CH₃ groups were calculated with absorption coefficients derived specifically for adsorbed hydrocarbon species, unlike previous studies, which employ absorption coefficients derived from liquid phase hydrocarbons. Results show that it is possible for reaction products to re-adsorb from the gas phase onto the support as well as spillover to the support from the active metal cobalt. Qualification and quantification of the chain length of these re-adsorbed species has shown that the support material (γ-alumina) selectively re-adsorbs shorter chain length species from the gas phase with a different functional group to the majority of observable species on a Co/Al₂O₃ catalyst. Comparison of Co/Al₂O₃ with Co/SiO₂, which utilises a more inert support relative to γ-alumina, shows that longer chained species are located on the cobalt metal itself during reaction and can be transported to the γ-alumina support via a process of spillover.

Introduction

The Fischer-Tropsch (FT) synthesis involves the catalytic reaction, at moderate temperatures and pressures, between CO and H₂ (collectively known as syngas) in order to produce liquid transportation fuels as the main products [1]. First discovered in the 1920’s [2,3], the process has become more popular in recent decades due the volatile economic nature of the oil and gas industry [4], as well as the need to continue to produce hydrocarbon fuels on
a large scale despite natural oil reserves becoming more difficult to recover. In industry, cobalt or iron are the common choices for the active component of the catalyst due to their high activity and low-cost, respectively [5,6]. Nickel [7] and ruthenium are also known to be active but instead are typically employed as promoters (amongst others such as Au, Cu, Mn, Pd, Pt) for the reaction [8–12]. Various metal oxides (Al₂O₃, SiO₂, and TiO₂) as well as carbon and zeolites have been extensively investigated as supports [13–16].

Despite being in use commercially since around the 1930’s, knowledge and understanding of FT synthesis is still somewhat limited and no single proposed reaction mechanism can account for all the experimental data [17,18]. This is, in part, due to the complex product distribution (which varies depending on the catalyst and reaction conditions) that is obtained and includes carbon product chain lengths from 1 to around 40-50. These products also include multiple functionalities such as alkanes, alkenes, branched isomers and numerous oxygenates.

A large proportion of studies have focussed on product analysis for FT synthesis using techniques such as gas chromatography (GC) [19] and mass spectrometry (MS) [20] in order to further understanding of the Anderson-Schulz-Flory (ASF) polymerisation behaviour which occurs [21,22]. Fewer reports however, have studied the catalyst itself during the course of the reaction. Fourier Transform Infrared (FTIR) spectroscopy is an ideal in-situ technique to study the catalyst during a reaction such as FT since the recording of spectra is not perturbed by the reaction conditions (i.e. temperature and pressure). FTIR has been utilised to gain qualitative information about the catalyst during FT synthesis, particularly to investigate adsorption sites of CO on supported FT catalysts [23,24]. Previously Jiang et al., employed Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS) to study manganese promoted cobalt [25] and iron [26] catalysts and found little or no evidence of adsorbed CO on either promoted or un-promoted cobalt or iron catalysts. This was ascribed to the dissociation of CO on very fine, reduced metallic particles. In contrast, previous work in this laboratory [27] and by other groups [28,29] have observed evidence for the adsorption of CO, using FTIR, on supported-cobalt catalysts under FT conditions.

Some studies have considered the CₓHᵧ stretching modes observed during the FT reaction. King [30] reported the presence of bands between 3100-2700 cm⁻¹ for supported Fe and Ru catalysts under FT conditions. For Ru/SiO₂, two intense bands were observed at 2930 and 2880 cm⁻¹ and were attributed to the asymmetric (asy) and symmetric (sym) stretching
modes of CH$_2$ species, respectively. On increasing the reaction temperature from 428 to 458 K, these bands decreased in intensity and eventually formed a broad band centred around 2930 cm$^{-1}$, assigned to a mixture of CH$_2$ and CH$_3$ groups, and a peak at 3015 cm$^{-1}$ associated with gas phase methane. In contrast, spectra of an Fe/SiO$_2$ catalyst only showed the broad band at 2935 cm$^{-1}$. With increasing temperature, shifts in the relative intensity of bands in the spectra towards lower CH$_2$:CH$_3$ intensities indicate shorter chain length species on the surface of the catalyst, which is consistent with the trend in FT products to decrease chain length with increasing temperature. Schanke et al. also reported similar observations for Fe and Ru/SiO$_2$ catalysts [24]. Prior to the work by King [30], Dalla Betta and Shelef [31], conducted similar experiments with Ru/Al$_2$O$_3$ catalysts and noted that even after the reaction had attained steady state, FTIR bands in the C$_x$H$_y$ region continued to grow, suggesting that these bands are due to reaction products or by-products which are adsorbed on the support. King [30] however, stated that there was insufficient evidence to determine whether these species were solely located on the alumina support. Much more recently, Lorito et al. [32] obtained spectra using a Co/Siralox catalyst under a flow of 2:1 H$_2$/CO mixture, at typical FT temperatures for Co catalysts (210-230°C). They consider the bands present for CH$_2$ species to be associated with long chain waxes which accumulated in the catalyst pores.

Few examples exist where the chain length, or quantity of these surface C$_x$H$_y$ species have been determined. Yamasaki et al. [33] calculated the average chain length of hydrocarbon species accumulated on a Ru/SiO$_2$ catalyst during the FT reaction. By calculating the amount of CH$_2$ and CH$_3$ units individually (note the authors tabulate quantity in units of volume, cm$^3$ at s.t.p, not moles), a ratio of the two amounts (CH$_2$:CH$_3$) resulted in an estimated average chain length of 4 after 3 min time on stream which grew to a value of 20 after 1 h and 30 after 3.5 h. Using a similar method, our group calculated the length of hydrocarbon species adsorbed on Au-promoted and un-promoted Co/Al$_2$O$_3$ catalysts [27,34]. Similar chain lengths of ca. 4.4 at steady state were calculated for both catalysts (225°C, 5 bar), however upon increasing the pressure to 10 bar, the average chain length at steady state increased to 5.9 [27]. In these examples [27,33,34], absorption coefficients calculated by Wexler [35] were used to determine the number of CH$_2$ and CH$_3$ units. These coefficients were derived using liquid phase hydrocarbons which might be expected to have a higher coefficient value than the species in an adsorbed form as a result of intermolecular interactions, and
therefore their use for adsorbed species may be inappropriate. This issue has been addressed in previous work [36] by attempting to calculate absorption coefficients for the vasy CH₃ and vasy CH₂ (2960 and 2925 cm⁻¹ respectively) modes for adsorbed hydrocarbon species. While a significant error (ca. 20%) was evident for the individual absorption coefficients, it was found that the ratio of these absorption coefficients (across multiple tests, various temperatures and over two different surfaces) have a significantly lower error (ca. 6%) and thus, the following expression was formulated to derive the average chain length of the hydrocarbon species using this absorption coefficient ratio:

$$\text{Average } CH₂: CH₃ \text{ ratio of } \text{adsorbed species} = \frac{A_{CH₂}}{A_{CH₃}} \cdot \frac{1}{\varepsilon_{CH₂}: \varepsilon_{CH₃}}$$  

Equation 1

where $A_{CHx}$ is the integrated absorbance of the band due to a particular stretching mode, and $\varepsilon_{CH₂}: \varepsilon_{CH₃}$ is the absorption coefficient ratio with a value of 0.36.

This study serves as the first of two parts where the location of the hydrocarbon species detected by FTIR spectroscopy has been investigated to determine where they reside on Co/Al₂O₃ and Co/SiO₂ catalysts during the FT reaction, i.e., are they found on the support material, metal or both. In addition, the above expression was applied to spectra collected during the course of the reaction in order to monitor the lengths of these species. In the second part, an attempt is made to link these findings to reaction data collected using on-line GC where reaction conditions as well as the active metal used were varied.

**Experimental**

**Catalyst synthesis**

Two 10 wt% loaded Co samples were prepared by wet impregnation of Co(NO₃)₂·6H₂O onto silica and alumina. For the Co/Al₂O₃ sample, γ-alumina (4.52 g) (Degussa) was wetted (20 ml of water) and stirred before Co(NO₃)₂·6H₂O (2.48 g) (BDH Chemicals Ltd.), which was dissolved in water (2.4 ml), was added drop-wise to the alumina slurry. After further stirring for approximately 40 min, the solution was left to dry slowly on top of a heating mantle (50°C) for 48 h. The sample was ground to a fine powder before calcination at 400°C in a flow (50 ml min⁻¹) of dry air. The Co/SiO₂ catalyst was prepared by the same method using Co(NO₃)₂·6H₂O (2.47 g) and silica (4.51 g) (Aerosil 200).

**Catalyst characterisation**

X-ray diffraction (XRD) patterns were collected using a X’Pert Pro diffractometer (Panalytical) with Cu Kα monochromatic radiation, using 0.013° steps within a 2θ range of
Temperature programmed reduction (TPR) analysis was carried out on a TPDRO 1100 Thermo Quest (CE Instruments). Co/Al₂O₃ (0.047 g) and Co/SiO₂ (0.053 g) samples were placed in a quartz reactor between a quartz wool plug. Reduction was carried out in a flow (20 ml min⁻¹) of a 5% H₂/N₂ mixture, and the sample heated from 40 to 800°C (10°C min⁻¹). Gravimetric analysis (to replicate the reduction conditions used in the reaction pre-treatment) was performed with a CI Precision MK2-G5 microbalance attached to a glass vacuum line used for gas manipulation. Powdered samples (ca. 40 mg) were loaded into a fritted bucket, before N₂ (25 ml min⁻¹) was introduced and the system heated to 350°C using a furnace (Watlow, 120 V). Once the mass had stabilised (2 h period) indicative of dehydration at this temperature, the N₂ was replaced by H₂ (20 ml min⁻¹) and continued for 2 h. Data for the mass recording were collected at a sampling rate of 120 min⁻¹. The mass difference between the point at which H₂ was introduced and after 2 h was taken as mass loss due to reduction (i.e. mass/moles of oxygen lost) with product water being removed at this temperature. The extent of reduction was calculated by:

\[
\% \text{ reduction} = \frac{\text{Moles of oxygen lost}}{\text{Initial moles of oxygen in sample}}
\]

Equation 2

Surface area measurements were collected using a Micromeritics Tristar 3000 following a pre-treatment in N₂ at 250°C for 2.5 h. N₂ adsorption isotherms were collected at -196°C between relative pressures of 0.05 and 1. The BET equation was then applied to the resulting data in order to determine surface areas. H₂ chemisorption of catalyst samples was performed using a Micromeritics ASAP 2020-C instrument. Initially samples underwent an in-situ reduction (350°C in H₂ for 2 h) before cooling to 35°C. Samples were then exposed to increasing pressures of H₂ (1-400 torr) to produce adsorption isotherms. Monolayer coverage was determined by fitting a Langmuir adsorption isotherm to the collected data assuming dissociative adsorption of H₂.

Fischer-Tropsch reaction

Sample powders were pressed into 13 mm diameter self-supporting discs, which were then loaded into a high-temperature, high-pressure FTIR cell (Specac). The consequences of variation in disc preparation in terms of quantification of alkyl species was described in an earlier, related publication [36]. Samples were heated to 350°C in a flow (12 ml min⁻¹) of N₂ gas. Once 350°C was attained, the gas flow was switched to H₂ (21 ml min⁻¹) for a 2 h reduction period, at which point the samples were then cooled to the reaction temperature.
(225°C). Syngas (H₂/CO = 2:1) was then introduced, initially at a high flow rate (ca. 240 ml min⁻¹) until the desired pressure was attained (by means of a back-pressure regulator and taking approximately 5 min to attain the desired pressure). After the pressure was stabilised, a flow rate of 11 ml min⁻¹ (gas hourly space velocity approximately equal to 40000 h⁻¹ – NB. gas flow is over a disc, and not through a fixed bed) was set and maintained for the duration of the reaction. Spectra were then collected at various times throughout the reaction using a Perkin Elmer 1700 FTIR Spectrometer at 4 cm⁻¹ resolution and an average of 25 spectra. An initial spectrum was collected after the sample pre-treatment, but before the introduction of syngas. This spectrum was subtracted from all subsequently collected spectra during the reaction in order to obtain “difference spectra”. The integrated absorbance for the bands due to the vasy CH₃ and vasy CH₂ modes were determined by deconvolution of the band envelope appearing in the 3100-2700 cm⁻¹ region. These derived integrated absorbances were introduced into Equation 1 in order to determine the average chain length of the surface species.

Results

Catalyst characterisation

Characteristics of the two samples are summarised in Table 1. The surface area of Co/Al₂O₃ and Co/SiO₂ after outgassing at 250°C for 2.5 h was calculated by application of the BET equation and were determined to be 86 and 163 m² g⁻¹, respectively (Table 1). Both values are lower than the parent support material (100 m² g⁻¹ for γ-alumina and 200 m² g⁻¹ for silica) implying some of the pores may be filled by the cobalt. Figure 1 shows the XRD pattern for both samples. A peak at 2θ = 36.9 is assigned to Co₃O₄ in both cases, however cobalt aluminates (CoAl₂O₄) are also known to have a cubic spinel phase like Co₃O₄ with the same diffraction peak positions [37]. Other peaks at 2θ = 18.9, 31.4, 44.9, and 59.5 are also assigned to various other planes of Co₃O₄ and a peak at 2θ = 45.7 present in the Co/Al₂O₃ pattern is indicative of γ-alumina phase [38]. The peak at 2θ = 36.9 was used to estimate the average crystallite size of Co₃O₄ using the Scherrer equation and resulted in crystallite sizes of 21.9 and 29.8 nm for Co/Al₂O₃ and Co/SiO₂, respectively (Table 1).

Figure 2 displays the TPR profiles for both catalysts. Both samples give two main reduction features at 340°C and a broad feature extending from about 500 to 700°C for Co/Al₂O₃ and at 325 and 360°C for Co/SiO₂. Jacobs et al. [39] explain through combined TPR-XANES/EXAFS
that the first, lower-temperature reduction feature can be assigned to the reduction of \( \text{Co}_3\text{O}_4 \) to \( \text{CoO} \), the presence of the former being consistent with XRD data (Figure 1). The second, higher-temperature reduction feature is strongly influenced by the nature of the support and represents the reduction of \( \text{CoO} \) to \( \text{Co}^0 \). The authors explain that this second reduction feature for \( \text{Co/SiO}_2 \) will occur at lower reduction temperatures relative to alumina-supported samples due to the weaker metal-support interaction, consistent with the profiles shown in Figure 2. As displayed in Table 1, the calculated degree of reduction from the TPR analysis is 71 and 100% for \( \text{Co/Al}_2\text{O}_3 \) and \( \text{Co/SiO}_2 \), respectively after a temperature ramp to 800°C. Analysis of the two stages for the fully reduced \( \text{Co/SiO}_2 \) sample showed that the first, lower temperature feature accounted for ca. 37% of the total uptake. This suggests that the two reduction features may overlap since only a quarter of the total hydrogen uptake is required in the first reduction step (\( \text{Co}_3\text{O}_4 \) to \( \text{CoO} \)) [39].

The gravimetric reduction analysis carried out to replicate the *in-situ* pre-treatment prior to the reaction showed the extent of reduction at 350°C to be 46 and 79% for \( \text{Co/Al}_2\text{O}_3 \) and \( \text{Co/SiO}_2 \), respectively. The data obtained from \( \text{H}_2 \) chemisorption resulted in uptake values of 12.0 and 19.8 \( \mu\text{mol g}^{-1} \) for \( \text{Co/Al}_2\text{O}_3 \) and \( \text{Co/SiO}_2 \) respectively, corresponding to particle sizes of 141 and 85 nm. However, this does not take into account the extent of reduction. Following the procedure of Reuel and Bartholomew [40], the particle size after reduction was calculated from the expression:

\[
d = \frac{C_1}{\%D} \quad \text{Equation 3}
\]

where \( C_1 \) is a constant associated with planar area of a cobalt atom based on the three most common crystallographic planes, the density and molecular weight of cobalt, \( d \) is the particle diameter (nm) and \( \%D \) is the percentage dispersion and is calculated from:

\[
\%D = \frac{C_2X}{Wf} \quad \text{Equation 4}
\]

where \( C_2 \) is a constant associated with cobalt based on the stoichiometry of hydrogen atoms on cobalt surface sites, \( X \) is the \( \text{H}_2 \) uptake (\( \mu\text{mol g}^{-1} \)), \( W \) is the weight percent loading of cobalt, and \( f \) is the fraction of cobalt reduced (values from gravimetric reduction analysis used). Use of this approach resulted in particle sizes of 30.9 and 32.4 nm for \( \text{Co/Al}_2\text{O}_3 \) and \( \text{Co/SiO}_2 \), respectively (Table 1) which is notably similar, but still larger than the crystallite sizes derived from XRD.

*Location of surface species*
Figure 3 (a) shows an initial FTIR spectrum collected prior to the reaction and a resulting spectrum (Figure 3 (b)) after 300 min under FT conditions carried out at 225°C, 10 bar using a Co/Al₂O₃ catalyst. Few features appear in the initial spectrum. A broad band between 3700-3100 cm⁻¹ for surface hydroxyl species is present as well as peaks at 1577 and 1460 cm⁻¹ which are attributed to carboxylate species present on the alumina support [41], which are assumed to be the result of carbonation during the calcination stage. After 300 min on stream, numerous other features become obvious, mainly the intense P and R branches of gas phase CO between 2250-2000 cm⁻¹ (present from the onset). Evidence of carboxylate growth is shown by an increase in intensity of the peaks at 1577 and 1460 cm⁻¹ as well as the appearance of new bands between 1400-1300 cm⁻¹ and a shoulder at 1650 cm⁻¹ which are representative of carboxylate and carbonate type species on the support. A small contribution due to the formation of gas phase CO₂ is shown between 2400-2300 cm⁻¹. The remaining bands between 3000-2750 cm⁻¹ are due CH₆ stretching modes and indicate the extent of formation of hydrocarbon species on the surface of the catalyst. Additional testing was carried out to determine the extent to which spectra collected during the reaction contained contributions due to gas phase hydrocarbons. A disc of the active Co/Al₂O₃ catalyst was situated in the FTIR cell, but out with the beam-path in order to determine whether gaseous species could be detected. Only a small intensity peak due to gas phase methane (3015 cm⁻¹) was observed.

Figure 4 shows difference spectra in the hydrocarbon region (3100-2700 cm⁻¹) collected over the duration of the reaction. The two most intense peaks at 2925 and 2860 cm⁻¹ are attributed to the vasy and vsym modes of CH₂, respectively and a shoulder at 2960 cm⁻¹ is indicative of the vsym mode of CH₃. There is also a small peak present at 3015 cm⁻¹ due to gas phase methane. The species detected by FTIR which result in the methyl and methylene stretching modes are attributed to adsorbed species which are accumulating on the catalyst surface. There are three possible descriptions to explain the location of these species on the catalyst surface:

1. Hydrocarbon chain growth on active metal sites.
2. Hydrocarbon chain growth on the active metal sites and spillover onto the catalyst support.
3. Hydrocarbon chain growth on the active metal sites followed by desorption and subsequent re-adsorption onto the catalyst support via the gas phase.
The term “hydrocarbon species” is employed in its broadest sense to imply a broad range of FT reaction products containing an alkyl chain including oxygenate species. It should be noted that species which are transported to the support may be subjected to further reactions. For example, alcohols have been shown to undergo dehydration on alumina [42]. The transportation of species detected from the active metal sites onto the support was proposed by Dalla Betta and Shelef [31]. In order to ratify if scenario 3 contributes to the resulting spectra, an experiment was carried out, whereby a disc composed of only γ-alumina (calcined at 400°C, 4 h) was positioned in the FTIR beam path, while elsewhere in the cell, a disc of active Co/Al₂O₃ was located out with the path of the FTIR beam but exposed to the same reactant gas stream and with the sample at reaction temperate. Band growth on the separate disc of γ-alumina should be evident if scenario 3 is taking place.

Figure 5 shows the band growth obtained on a separate disc of γ-alumina and thus participation of scenario 3 is confirmed. Similar peak positions as observed for the Co/Al₂O₃ catalyst for vasy CH₃, CH₂ and vsym CH₂ at 2960, 2925 and 2860 cm⁻¹, respectively, as well as gas phase methane at 3015 cm⁻¹. In addition, peaks are present at 2906 cm⁻¹ and a shoulder at 2885 cm⁻¹ which are attributed to a methine (CH) stretching mode and the vsym CH₃ mode, respectively. The appearance of a band due to a methine stretching mode where a sample of γ-alumina was present, but which was not observed for Co/Al₂O₃, would suggest the presence of a species with a different structure. Other bands observed when adsorption on the alumina sample is monitored support the conclusion of differentiation between species adsorbed on the support and the Co/Al₂O₃. These also include bands due to CH stretching mode of aldehydes at ca. 2750 cm⁻¹ and a band assigned to an olefinic =CH₂ stretching mode at 2995 cm⁻¹. It should be noted, however, that the intensities of bands when directly monitoring the Co/Al₂O₃ (Figure 4) are roughly an order of magnitude larger than when monitoring the alumina alone (Figure 5). Therefore the presence of these additional bands may be difficult to detect in the case of the Co/Al₂O₃, in part, due to the predominance of other features which, apparently, are not transferred through the gas phase for re-adsorption onto the support.

A comparison of the length of these hydrocarbon chains (determined using Equation 1) generated using either the active sample (Figure 4) or the alumina alone with the active material out with the FTIR beam (Figure 5), is shown in Figure 6. In both cases there is an
initial induction period during the first 3-4 h where the average chain length grows, followed by a decrease in the growth rate followed by a plateau. The initial chain length is around 4.7 after 5 min for the Co/Al₂O₃ catalyst, but increases in length to about 7 after 225 min before becoming constant. In contrast, the species detected on the surface of the separate disc of alumina undergo very little progressive growth and are comparably shorter in length to Co/Al₂O₃, starting with an average chain length value of 3.1 after 10 min and growing to around 4 units. The amount of adsorbed species was also quantified using the following equation (see reference [34] and references within):

\[ \varepsilon = \frac{A C_d}{n r m} \]  

Equation 5

where \( \varepsilon \) is the molar absorption coefficient (cm \( \mu \text{mol}^{-1} \)), \( A \) is the integrated absorbance of the particular mode (cm\(^{-1}\)) – determined by deconvolution of the spectra, \( C_d \) is the area of the sample disc (cm\(^2\)), \( n_r \) is the number of adsorbed species (\( \mu \text{mol g}^{-1} \)) and \( m \) is the initial mass (g) of the sample. \( C_d \) was determined using imaging software, ImageJ, which calculates an area based on a user-defined section of a photograph, with known dimensions (in pixels). It should be noted that the absorption coefficients, \( \varepsilon \), used for vasy CH₃ (3.01 cm \( \mu \text{mol}^{-1} \)) and vasy CH₂ (1.08 cm \( \mu \text{mol}^{-1} \)) have a 19 and 20% error attributed to them, respectively [36]. The calculated amounts of adsorbed CH₅ (\( \mu \text{mol g}^{-1} \)) on Co/Al₂O₃ and \( \gamma \)-alumina are displayed in Figure 7. For both adsorbents, the individual amounts of CH₂ and CH₃ species continued to grow up to 360 min whereas the average chain length for both adsorbents plateaued after about 225 min (Figure 6). This suggests that between 225 and 360 min more species but of an equivalent chain length are adsorbed.

Analogous experiments were carried out using silica, selected as an example of a more inert support material. Figure 8 shows a selection of spectra collected during reaction for both a Co/SiO₂ catalyst and a disc of silica alone (calcined at 400°C, 4 h) where the Co/Al₂O₃ was present elsewhere in the cell, out with the path of the FTIR beam. Quantification of the species adsorbed to the Co/SiO₂ catalyst is also presented (Figure 8). The poorer signal-to-noise (S/N) ratio for the spectra arising from the re-adsorbed species on the separate disc of silica, are a consequence of the lower uptake of adsorbate, reducing the confidence levels of the accuracy of deconvolution.
Spectra (Figure 8 top) for Co/SiO$_2$ (left) and a separate disc of silica (right), show peaks at 2928 and 2860 cm$^{-1}$ due to vasy and vsym CH$_2$ modes, respectively. A peak due to gas phase methane (3015 cm$^{-1}$) is again evident in the spectra collected for the separate disc of silica, as well as a more obvious shoulder at 2960 cm$^{-1}$ due to the vasy CH$_3$ mode than that detected for Co/SiO$_2$. The shape of the band envelope using the separate disc of silica would suggest the presence of similar species to those observed on Co/Al$_2$O$_3$ and Co/SiO$_2$, unlike that for the case of the separate disc of γ-alumina. The average chain length of the species adsorbed on Co/SiO$_2$ (Figure 8 bottom left) increases during the first 200 min from an initial value of ca. 8 after 50 min (first data point after 50 min due to poor S/N ratio prior to this), before becoming more constant at an approximate value of 9 (2 carbon units longer than the Co/Al$_2$O$_3$ equivalent). Quantification of the amount of CH$_3$ observed on the Co/SiO$_2$ catalyst, (26 µmol g$^{-1}$ - Figure 8, bottom right) is considerably less that that observed on Co/Al$_2$O$_3$ (243 µmol g$^{-1}$ - Figure 7).

**Discussion**

Characterisation of Co/Al$_2$O$_3$ and Co/SiO$_2$ catalysts showed the initial oxidic state of cobalt to be Co$_3$O$_4$ using XRD (Figure 1). TPR profiles (Figure 2) suggest a primarily two-step reduction of Co$_3$O$_4$ (i.e., Co$_3$O$_4$→CoO→Co$^0$) takes place, in agreement with the observations of Jacobs et al. [39]. However, additional reduction features, which may also be apparent for Co/Al$_2$O$_3$ (Figure 2), include shoulders which are apparent at 400 and 500°C. These features may be explained by the reduction of other cobalt species which may be present after an initial reduction step which may include Co$^{3+}$ and Co$^{2+}$. Indeed, Arnoldy and Moulijn [43] reported four individual regions for the reduction of alumina-supported cobalt catalysts; 1) Co$_3$O$_4$ reduction at 327°C, 2) Co$^{3+}$ reduction at 477°C, 3) Co$^{2+}$ reduction at 627°C and finally 4) reduction of cobalt aluminates at 877°C. Although the reduction temperatures reported by Arnoldy and Moulijn do not match those observed in this study, the authors detail the effect of preparation methods (e.g. calcination temperatures and flow rates) on the reduction temperatures. The Co/SiO$_2$ catalyst is fully reduced using a temperature programme which reached 800°C, while the Co/Al$_2$O$_3$ catalyst was only 71% reduced (Table 1). These variations are due to the different metal-support interactions associated with alumina and silica, where the latter are relatively weaker, and therefore will result in more
facile reduction [39]. A comparison of the TPR profiles (Figure 2) suggests that the use of a silica support facilitated a much lower reduction temperature for the second reduction step, which decreased from a broad feature for Co/Al₂O₃ between 500 and 700°C to a sharp feature centred at 360°C for Co/SiO₂. A much smaller shift for the first reduction feature was evident - 340°C for Co/Al₂O₃ compared to 325°C for Co/SiO₂. Based on the amount of hydrogen consumed (37%) for the first reduction feature for the Co/SiO₂ catalyst, it is assumed that an overlap of the reduction steps occurred. Under reduction conditions identical to those used for the FT reaction, again Co/Al₂O₃ proved more difficult to reduce than Co/SiO₂ (46 versus 79% reduction). Particle size analysis, using data from H₂ chemisorption as well as the gravimetric reduction analysis, resulted in very similar estimated particle sizes for both the alumina and silica-supported catalysts (30.9 and 32.4 nm respectively).

The location of adsorbed hydrocarbons on supported cobalt catalysts during the FT reaction were investigated by in-situ FTIR. Analysis of a Co/Al₂O₃ catalyst, produced spectra (Figure 4) where CH₂ (asy and vsym modes at 2928 and 2860 cm⁻¹, respectively) appeared to be the dominant fragments in the spectra collected in the range 3100-2700 cm⁻¹. Also present was the band due to the vsym mode of CH₃ (2960 cm⁻¹). These are predominantly indicative of hydrocarbon reaction products which have adsorbed to the catalyst, or more specifically to the support, as reported by Dalla Betta and Shelef [31] when investigating the FT reaction using in-situ IR on a Ru/Al₂O₃ catalyst. King [30] stated that there was insufficient evidence to confirm that the hydrocarbons were only adsorbed to the support and that they could in fact be present on the metal as well. In this study, the use of the “separate disc” experiment and the use of alternative supports have allowed further insight into this issue. Band growth occurred over the duration of a reaction when a disc of the support material, γ-alumina, was present in the path of the FTIR beam (Figure 5), while elsewhere in the cell, FT active Co/Al₂O₃ catalyst was s present. Band growth on the separate disc of alumina would only happen, if some of the reaction products re-adsorb to the support from the gas phase, hence scenario 3 (as referenced earlier) is proven. The spectra collected using the disc of γ-alumina resulted in a different band envelope in comparison to the Co/Al₂O₃ catalyst. The presence of bands due to methine (2906 cm⁻¹), bands due to CH stretching mode of aldehydes (ca. 2750 cm⁻¹) and olefinic =CH₂ stretching mode (2995 cm⁻¹), which are not present (or at least in any significant, observable amount relative to the intensities of other
bands which are present) on the Co/Al₂O₃ sample, would suggest a different hydrocarbon species has re-adsorbed on the support material. With evidence of re-adsorption of reaction products to the support from the gas phase, those species should indeed be present on the Co/Al₂O₃ sample. However, the shapes of the band envelope in spectra for the Co/Al₂O₃ sample are vastly different to that on the separate disc of γ-alumina. Therefore it can be said that the spectra obtained for the Co/Al₂O₃ must be a combination of re-adsorbed products which have re-adsorbed on the support from the gas phase as well as hydrocarbons which reside on the active metal and/or species which are transported to the support by other means, i.e. spillover. Table 2 summaries the average hydrocarbon chain length present on the various adsorbents tested using Equation 1 for the initial and final data points. The average length of adsorbed products on the Co/Al₂O₃ catalyst was shown to grow by 2.6 carbon units over the duration of the reaction, with a maximum value of 7.3 reached after 225 min time on stream. In comparison, very little growth was shown for the separate disc of γ-alumina, with a maximum value of 3.9 attained which initially began at 3.1. These re-adsorbed products are therefore suggested to be selectively adsorbed, shorter chained species which differ in structure compared to the majority of the species observed on the Co/Al₂O₃ catalyst. Since, as discussed, the spectra obtained using a Co/Al₂O₃ catalyst are a combination of re-adsorbed products and other hydrocarbons located elsewhere, the calculated average value for the chain length for Co/Al₂O₃ must be reduced as a consequence of the presence of these shorter chained products re-adsorbed on the support (i.e. there are other longer chained hydrocarbon fragments on the Co component). When analogous tests were carried out using a separate disc of silica, re-adsorption had occurred, but in a quantity too insignificant to quantify. Therefore, with little re-adsorption to the silica support, it is suggested that the chain lengths determined using the Co/SiO₂ catalyst are more indicative of the hydrocarbons which reside on the active cobalt metal and would be expected to be longer than those observed on the Co/Al₂O₃ catalyst. Indeed, for the Co/SiO₂ catalyst, the calculated average chain length reached a maximum of 9.3 as compared to 7.3 calculated for Co/Al₂O₃.

The number of moles of CH₂ and CH₃ adsorbed on Co/Al₂O₃ and the γ-alumina support as determined by use of Equation 5 are shown (Figure 7). If it is assumed that a hydrocarbon chain attached to the surface of the catalyst terminates in a CH₃ group, then the number of CH₃ fragments would equal the total number of adsorbed hydrocarbon fragments (this
assumes the absence of branched chained products). Therefore, the data (Table 2) would suggest that there is approximately 5-fold more individual hydrocarbon chains adsorbed on the Co/Al₂O₃ catalyst compared to the separate disc of γ-alumina after 360 min (243 μmol g⁻¹ of CH₃ on Co/Al₂O₃ and 45 μmol g⁻¹ of CH₃ on γ-alumina). The percentage of the carbon in the feed stream which is retained on the surface of the Co/Al₂O₃ catalyst can be calculated based on these estimations. If the average CH₂:CH₃ ratio is 7 after 360 min, which would indicate an actual chain length of 8, then the total number of moles of carbon can be determined and compared to the total amount of carbon (in the form of CO) introduced to the reactor. It is estimated that 0.01% of the total inlet carbon is retained on the Co/Al₂O₃ catalyst surface.

Surface coverages may be calculated if it is assumed that the adsorption sites for the hydrocarbon fragments on the support are hydroxyl groups. Digne et al. [44] report a range of surface hydroxyl group densities from 12.0 at 177°C to 4.9 OH nm⁻² at 607°C for standard γ-alumina. Having calcined the Co/Al₂O₃ catalyst at 400°C (the highest temperature treatment applied to the catalyst), a hydroxyl concentration of 8.3 OH nm⁻² is suggested for the support material. However, it should be noted that this value is not definitive due to, for example, water being produced during the reduction of the catalyst (or the FT reaction itself) which may alter this value. Based on this hydroxyl group concentration, the coverage, θ, was calculated using:

$$\theta = \frac{\text{No. of CH₃ groups}}{\text{No. of OH surface sites}}$$  

Equation 6

The extent of coverage on the γ-alumina support due to re-adsorption of gaseous reaction products was determined to be θ = 0.03 and 0.05 after 360 and 1440 min, respectively. In comparison, the coverage for Co/Al₂O₃ was found to be considerably higher at θ = 0.21 after 360 min and θ = 0.42 after 1440 min. Applying the H₂ chemisorption data to the Co/Al₂O₃ catalyst used, the number of available surface Co atoms is determined to be 1.08 x 10¹⁷. In comparison to the amount of CH₃ groups calculated after 360 min for Co/Al₂O₃, the number of exposed Co atoms is 20 times less and 41 times less after 1440 min than the number of hydrocarbon fragments. It should be stated that this assumes that each available Co atom can accommodate a hydrocarbon chain which may not be possible due to, for example,
steric hindrance. When considering this as well as comparing the coverages observed on the γ-alumina support and the Co/Al₂O₃ catalysts, it would suggest that a considerable amount of species must spillover to the support.

To consider spillover from active metal cobalt particles to the support for a Co/Al₂O₃ catalyst, the radial distance from a cobalt particle that the total number of hydrocarbons (based on the number of CH₃ units present) must diffuse across in order to attain a 1:1 ratio of CH₃:OH for the coverages calculated and a theoretical full coverage, i.e. θ = 1, is shown in Figure 9. The data shown (Figure 9) was determined by calculating the number of OH groups in a circular area, excluding the area of the cobalt particle, and then scaled up to apply for the catalyst as a whole based on the total number of cobalt particles. By comparing with the estimated number of CH₃ groups present at various reaction times, the maximum distance that a hydrocarbon species would have to diffuse across the surface in order to account for a 1:1 ratio of CH₃:OH can be calculated. Assuming an OH concentration of 8.3 nm⁻² after 360 min (21% coverage), a radius of 80 nm from the centre (or 64.5 nm from the edge) of the cobalt particle would be required in order to attain a 1:1 ratio. After 1440 min (42% coverage), 112.5 nm from the centre (or 97 nm from the edge) of the cobalt particle would be required and at complete surface coverage, 175 nm from the centre (or 159.5 nm from the edge) of the cobalt particle would attain a 1:1 ratio. Additional OH concentrations have also been modelled (4.9 and 12.0 OH nm⁻² - Figure 9). It is evident that at lower OH concentrations, migration of the species appears to occur over a large distance since the adsorption sites are spread further apart, and conversely at higher OH concentrations, the species do not have to migrate as far to obtain a 1:1 CH₃:OH ratio. This model makes the assumptions that none of the hydrocarbon chains contain any branches which would alter the CH₃:OH ratio, and that all of the species are indeed spilled over to the support (which has already been shown not to be the case due to re-adsorption from the gas phase). As stated, after 360 min (21% coverage), a radius of 80 nm from the centre of the cobalt particle would suffice for a 1:1 CH₃:OH ratio for an OH concentration of 8.3 OH nm⁻². This appears to be a large distance to diffuse across the surface, however, giving that even after only 360 min, the amount of CH₃ (243 μmol g⁻¹ - Table 2) outnumbers the sum of the available Co sites (12 μmol g⁻¹ - Table 1) and the quantity of re-adsorbed species from the gas phase (45 μmol g⁻¹ - Table 2), a scenario by which the hydrocarbons migrate large distances across the support should be considered. In a review by Conner and Falconer
the migration of spilt over species is discussed and although the transfer of species over large distances is debated, examples are known where spill-over hydrogen has been shown to travel over millimetres or even centimetres on silica surfaces [46]. Conner and Falconer [45] describe a “bucket brigade” like transport whereby hydrogen diffusion across an oxide surface is facilitated by surface hydroxyl groups.

It should also be noted that, the length of adsorbed hydrocarbons on FT catalysts have been previously calculated [27,33] utilising absorption coefficients [35] which were determined from liquid phase hydrocarbon compounds. In separate tests [27], an initial CH$_2$:CH$_3$ ratio of 2.9 was found, which rose to a constant value of 5.9 for a 10 wt% Co/Al$_2$O$_3$ catalyst under analogous conditions (225°C, 10 bar, H$_2$/CO = 2:1), using Wexler’s [35] coefficients. These chain lengths are shorter in comparison to the initial (4.9) and final (7.3) values determined in this study. This difference is attributed to the use of liquid phase derived absorption coefficients (where a larger vibrational response per mole would be expected relative to the adsorbed form) being applied to adsorbed species.

Conclusions

**In-situ** FTIR spectroscopy was implemented to investigate the location, length and amount of hydrocarbon species detected at the surface of supported-cobalt catalysts during the FT reaction. The use of the “separate disc” experiment showed it was possible for species to be transported to the γ-alumina support of a Co/Al$_2$O$_3$ catalyst by re-adsorption of products from the gas phase. A qualitative comparison of the species present in spectra collected from the Co/Al$_2$O$_3$ and the separate disc of γ-alumina suggests that the re-adsorbed species are of a differing structure to the majority of species observed for Co/Al$_2$O$_3$. In addition, the average length of the re-adsorbed species was determined to be significantly shorter than those observed for Co/Al$_2$O$_3$. Quantification of hydrocarbons observed on a Co/SiO$_2$ catalyst, where silica acts as a much more inert support, suggested that longer chained species reside on the cobalt metal itself. Through quantifying the individual hydrocarbon chains, it was evident that not all of the observed hydrocarbons remain on the available cobalt sites and that transfer and re-adsorption of the products to the γ-alumina support would likely only account for a small fraction of the total number of hydrocarbon species. The possibility of hydrocarbon chains spilling over to the support via surface diffusion from
the cobalt metal was postulated, and shown to occur, possibly over large distances. Further work is to be conducted where any link between the hydrocarbon species observed by FTIR and reaction products is to be investigated.
