Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

3
4 ABSTRACT. We report a study using Pt(111) and Pt(100) electrodes of the role of
5
6
7 adsorbed formate in both the direct and indirect pathways of the electrocatalytic
8
9
10 oxidation of formic acid. Cyclic voltammetry at different concentrations of formic acid
11
12
13 and different scan rates, as well as pulsed voltammetry, were used to obtain a deeper
14
15
16 insight into the effect of formate coverage on the rate of the direct pathway. Pulsed
17
18
19 voltammetry also provided information on the effect of the concentration of formic acid
20
21
22 on the rate of formation of adsorbed CO on Pt(100). At low to medium coverage,
23
24
25 increasing formate coverage increases the rate of its direct oxidation, suggesting that
26
27
28 decreasing the distance between neighboring bidentate adsorbed formate favors its
29
30
31 interconversion to and/or stabilizes monodentate formate (the reactive species).
32
33
34
35 However, increasing the formate coverage beyond approximately 50% results in a
36
37
38 decrease of the rate of the direct oxidation, probably because bidentate formate is too
39
40
41 closely packed for its conversion to monodentate formate to be possible. Cyclic
42
43
44 voltammetry at very high scan rates reveals the presence of an order-disorder phase
45
46
47 transition within the bidentate formate adlayer on Pt(111) when the coverage
48
49
50 approaches saturation. The dependence of the potential of maximum rate of

1
2
3 dehydration to adsorbed CO, and of the rate at the maximum, on the concentration of
4
5
6
7 formic acid is in good agreement with predictions made for a mechanism in which
8
9
10 adsorbed CO is formed through the adsorption of formate followed by its reduction to
11
12
13
14 adsorbed CO, thus confirming that monodentate adsorbed formate is the last
15
16
17 intermediate common to both the direct and indirect pathways.

26 27 **1. INTRODUCTION** 28 29 30

31 The electrocatalytic oxidation of formic acid on platinum electrodes is among the
32
33
34 electrochemical reactions that has attracted most interest for a long time.¹⁻² The main
35
36
37 reasons for this long-standing interest are (i) the relative simplicity of the reaction (only
38
39
40 two electrons and two protons need to be transferred for its complete oxidation to CO₂)
41
42
43
44 and (ii) the possibility of using formic acid as a liquid fuel in fuel cells. Moreover, the
45
46
47 knowledge gained in the study of this oxidation reaction can be transferred to those of
48
49
50
51
52 other, more complex, organic molecules.
53
54
55
56
57
58
59
60

1
2
3
4 The formation of a catalytic poison during the oxidation of formic acid on platinum was
5
6
7 proposed as early as 1928 based on the oscillatory behavior of the reaction³ (92 years
8
9
10 later, the formic acid oxidation reaction remains the archetype electrochemical
11
12
13 oscillator), but Capon and Parsons⁴ were the first to propose that the reaction must
14
15
16 proceed through two possible parallel pathways, one leading directly to the formation of
17
18
19 CO₂ without breaking any of the C–O bonds (the so-called direct path) and a second
20
21
22 one in which an adsorbed species that acts as a catalytic poison is formed and then
23
24
25 oxidized to CO₂ (the so-called indirect path). The actual adsorbate responsible for the
26
27
28 poisoning of the Pt surface was the subject of intense debate for some time, until *in situ*
29
30
31 infrared reflection absorption spectroscopy (IRRAS) provided unambiguous proof that
32
33
34 the catalytic poison is adsorbed carbon monoxide⁵ (*i.e.*, the indirect path involves the
35
36
37 dehydration of formic acid to yield adsorbed CO, which must then be oxidized to CO₂ to
38
39
40 complete the reaction).
41
42
43
44
45
46
47
48
49

50 Identification of the species mediating the direct path and the formation of adsorbed CO
51
52
53 took much longer. In 2002 Miki et al.⁶ detected for the first time, using surface-enhanced
54
55
56
57
58
59
60

1
2
3 infrared absorption spectroscopy in the attenuated total reflection configuration (ATR-
4
5
6
7 SEIRAS), the presence of bidentate adsorbed formate on the surface of a Pt electrode
8
9
10 during the oxidation of formic acid, and proposed it to be the intermediate in the direct
11
12
13 pathway. Later, based on the very good correlation between the rate of formation of
14
15
16 adsorbed CO and the coverage by adsorbed bidentate formate as determined by ATR-
17
18
19 SEIRAS, Cuesta et al.⁷⁻⁸ suggested that this species is also the intermediate in the
20
21
22 dehydration of formic acid (in other words, that this species corresponds to the point
23
24
25 where the reaction separates into two pathways).
26
27
28
29
30
31

32 The correlation between the reaction rate and the coverage by this species seemed to
33
34
35 support these claims, but work by others suggested that bidentate adsorbed formate is
36
37
38 too stable to be the reactive intermediate⁹⁻¹⁰ and the activation energy for breaking the
39
40
41 C-H bond in this species is far too high¹¹ for it to be the intermediate in any of the two
42
43
44 paths. Chen et al. performed ATR-SEIRAS experiments coupled with a thin-layer
45
46
47 electrochemical flow cell and proposed that formate would be a spectator species in a
48
49
50 so-called “three pathway mechanism” in which the active intermediate would be
51
52
53
54
55
56
57
58
59
60

1
2
3 different from adsorbed formate.¹²⁻¹³ This was supported by further experiments by
4
5
6
7 Okamoto et al.¹⁴ and DFT calculations by Neurock et al., who suggested that adsorbed
8
9
10 formate is relatively stable and proposed that a carboxylic acid species adsorbed
11
12
13 through the carbon atom (-COOH) would be the active species.¹⁵ More recently, Chen
14
15
16 et al. suggested, based on modeling of galvanostatic potential oscillations, that the
17
18
19 reactive intermediate in the direct pathway would be an unspecified anionic species.¹⁶
20
21
22
23
24 However, neither -COOH nor other intermediate species different from formate have
25
26
27
28 been experimentally detected, and the dependence of the reaction rate on the pH of the
29
30
31 electrolyte has unambiguously demonstrated that formate is the reactive intermediate.
32
33
34
35 Since formate can adsorb in either monodentate or bidentate configuration, it has been
36
37
38 proposed that the former is the actual reaction intermediate.¹⁷⁻²¹ Bidentate formate is
39
40
41 nonetheless not a dead end, as it can still affect the reactivity by being in equilibrium
42
43
44 with the reactive intermediate and/or contributing to stabilizing the reactive intermediate
45
46
47
48 in its neighborhood²¹⁻²². Monodentate adsorbed formate has also been suggested to be
49
50
51 the intermediate leading to adsorbed CO,²³⁻²⁴ *i.e.*, to play the role of the last common
52
53
54
55 intermediate in the dual path initially assigned⁷⁻⁸ to bidentate formate.
56
57
58
59
60

1
2
3 We report here a detailed study using Pt(111) and Pt(100) electrodes, cyclic
4
5
6
7 voltammetry and pulsed voltammetry that provides further insight into the roles of both
8
9
10 forms of adsorbed formate in the formic acid oxidation reaction. We show that
11
12
13
14 adsorption of formate is necessary for both pathways to proceed and that only at high
15
16
17 coverage does bidentate formate become a blocking species. Our results regarding the
18
19
20 dependence of the potential at which the rate of dehydration is maximum and of the rate
21
22
23 of dehydration at that maximum on the concentration of formic acid are in good
24
25
26 agreement with previous predictions⁸ based on a mechanism for the indirect path in
27
28
29 which the adsorption of formate is followed by its reduction to adsorbed CO.

34
35

36 2. EXPERIMENTAL SECTION

37
38
39

40 The platinum single-crystal electrodes, namely Pt(111) and Pt(100), were prepared
41
42
43 from small Pt beads ca. 2 mm in diameter, following the method described by Clavilier
44
45
46 et al.²⁵ Before every measurement, the electrode was flame annealed, cooled in an
47
48
49 Ar/H₂ (3:1) atmosphere and protected with an ultrapure water drop saturated with these
50
51
52
53
54 gases. They were then transferred to the glass electrochemical cell. This preparation
55
56
57
58
59
60

1
2
3 procedure assures that the obtained experimental surfaces correspond to the nominal
4
5
6
7 topographies.²⁶ All measurements have been conducted using a Pt counter electrode
8
9
10 and a reversible hydrogen electrode (RHE) as reference.
11
12

13
14 The solutions were prepared using 60% HClO₄ (Merck, for analysis), HCOOH (Merck,
15
16 for analysis), H₂SO₄ (Merck, suprapur) and ultrapure water (Elga PureLab Ultra, 18.2
17
18 MΩ cm). Electrochemical measurements were carried out by using a signal generator
19
20
21 EG&G PARC and eDAQ EA161 potentiostat with an Edaq e-corder ED401 recording
22
23
24 system. Experiments in hydrodynamic conditions were performed with the hanging-
25
26
27 meniscus rotating disk electrode (HMRDE) configuration using an EDI101 rotating
28
29
30 electrode and a Radiometer CTV 101 for controlling the rotation rate (both from
31
32
33 Radiometer Analytical). All experiments were carried out at room temperature.

44

45 3. RESULTS AND DISCUSSION

46
47
48
49 **3.1. Adsorbed formate in the direct path.** Although qualitatively Pt(111) and Pt(100)
50
51
52
53 electrodes behave similarly for the formic acid oxidation reaction, there are significant
54
55
56
57
58
59
60

1
2
3 differences in the dependence of the measured currents on the applied potential and
4
5
6
7 the concentration of formic acid. These differences are evident even when simply
8
9
10 comparing the voltammetric profiles the Pt(111) and Pt(100) electrodes in the presence
11
12
13 of formic acid. Figure 1A shows a typical cyclic voltammogram (CV) of Pt(111) in the
14
15
16 presence of 0.05 M HCOOH. It is important to highlight that the profiles do not change
17
18
19 with successive cycling for all the electrodes used in this study, indicating the absence
20
21
22
23 of possible contaminants and the stability of the surfaces in the potential window
24
25
26
27 employed. For the Pt(111) electrode, currents in the positive and negative scan
28
29
30 directions are almost identical, which indicates that the formation and accumulation of
31
32
33 CO on the surface at low potentials is negligible. In fact, it has been shown that on
34
35
36 Pt(111) electrodes the formation of CO only takes place at measurable rates on defect
37
38
39 sites.²⁷
40
41
42
43
44
45

46 The Pt(100) electrode is significantly more active for the oxidation of formic acid
47
48
49 through the direct path than the Pt(111) surface, as revealed by the considerably higher
50
51
52 current densities achieved in the negative scan direction (Figure 1B). Moreover, the
53
54
55
56
57
58
59
60

1
2
3 Pt(100) surface is also very active for the formation of adsorbed CO at low potentials,²⁸
4
5
6
7 as revealed by the negligible oxidation currents recorded in the positive scan direction.
8
9

10 At potentials below 0.4 V, Pt(100) is a more active catalyst than Pt(111) for the
11
12
13 dehydration of formic acid to adsorbed CO, resulting in poisoning of the catalyst and a
14
15
16
17 very low activity for the dehydrogenation of formic acid to CO₂ in the positive-going
18
19
20
21 scan.²⁷ It should be noted that the actual currents measured in the first scan depend
22
23
24 strongly on the time required to form the hanging meniscus and start the CV. Slightly
25
26
27
28 higher currents can be measured when the meniscus is formed and the scan started
29
30
31 rapidly. Above 0.8 V, oxidative stripping of adsorbed CO reactivates the surface for the
32
33
34
35 oxidation of formic acid. In the negative scan direction, high currents are measured
36
37
38
39 which are associated with the oxidation of formic acid through the active intermediate.
40
41
42 Below 0.5 V, the current diminishes due to the combination of three different factors: (i)
43
44
45 the lower overpotential, (ii) the less favorable adsorption of formate in both bidentate
46
47
48
49 and monodentate configurations (see below) and (iii) CO poisoning.²⁸
50
51
52
53
54
55
56
57
58
59
60

Figure 1. Voltammetric profiles at 0.05 V s^{-1} and 1600 rpm in $0.1 \text{ M HClO}_4 + 0.05 \text{ M HCOOH}$ of the Pt(111) (A) and Pt(100) (B) electrodes in a HMRDE configuration.

These voltammetric profiles must be analyzed in view of the mechanism of the reaction, for which it is generally accepted that the active intermediate is monodentate adsorbed formate.¹⁷⁻²¹ As aforementioned, formate can also be adsorbed in a bidentate configuration,⁶⁻⁸ which is the most stable form but also very unreactive.⁹⁻¹¹ Adsorbed formate in the monodentate form can evolve either to the formation of CO_2 or to the bidentate form. The latter, which would deactivate the species, is inhibited by the

1
2
3 presence of other neighboring adsorbed species, including other specifically adsorbing
4
5
6
7 anions and bidentate formate itself.²¹⁻²² Thus, the electrocatalytic oxidation of formic
8
9
10 acid requires the adsorption of formate in the monodentate form and its stabilization by
11
12
13 the presence of neighboring adsorbed molecules, such as formate in the bidentate
14
15
16
17 configuration, to prevent its transformation into the unreactive form.²¹
18
19
20
21

22 The increase and subsequent decrease of the current corresponding to the direct path
23
24
25 in the negative scan is sharper for Pt(100) than for Pt(111), which, according to the
26
27
28 proposed mechanism, should be related to differences in the adsorption behavior of
29
30
31
32 formate on the two surfaces. The adsorption of formate, whether from formic acid
33
34
35 (Reaction (2)) or from formate at higher pH or after the dissociation of HCOOH
36
37
38 (Reaction (3)), involves the transfer of one electron, and, as happens with the specific
39
40
41
42 adsorption of most, if not all, anions, is a very fast, equilibrium process
43
44
45
46

1
2
3 Recently accumulated evidence regarding the dependence of the rate of oxidation of
4
5
6
7 formic acid on the electrolyte pH¹⁸⁻²⁰ suggests that HCOO⁻, and not HCOOH, is the
8
9
10 active species, i.e., that dissociation of HCOOH ($\text{HCOOH} \rightleftharpoons \text{HCOO}^- + \text{H}^+$) precedes the
11
12
13 formation of adsorbed formate, which is therefore better described by Reaction (3).
14
15
16
17

18 The current due to the adsorption of formate has, therefore, a pseudocapacitive
19
20
21 nature, and will scale linearly with the scan rate. On the contrary, the current for the
22
23
24 overall direct oxidation process scales with the square root of the scan rate, as it
25
26
27 involves the diffusion of formic acid to the electrode surface. At very low scan rates, the
28
29
30 current in the CV is overwhelmingly dominated by that corresponding to the overall
31
32
33 faradaic process (see, e.g., CVs at 50 mV s⁻¹ in Figure 1). However, if the scan rate
34
35
36 increases, the pseudocapacitive current eventually becomes significantly higher than
37
38
39 that due to the faradaic process and dominates the CV. An equivalent explanation is
40
41
42 that, as the rate-determining step is the oxidation of monodentate adsorbed formate to
43
44
45 CO₂, the scan rate can eventually become too fast for this process to be observed, and
46
47
48
49
50 the electroadsorption of formate is the only process contributing to the current in the CV.
51
52
53
54
55
56
57
58
59
60

1
2
3
4 In the case of the Pt(111) electrode, this strategy enables to observe and analyze the
5
6
7 formate adsorption process.²⁹ As can be seen in Figure 2A, as the scan rate increases,
8
9
10 the shape of the CV evolves towards that typical of anion adsorption. In fact, the shape
11
12
13 measured at 40 V s⁻¹ resembles that obtained for acetic acid solutions for the same
14
15
16 electrode.²⁹ When the current is normalized by the scan rate, the CVs between 0.06 and
17
18
19 0.35 overlap at all scan rates, because this region correspond to the hydrogen
20
21
22 adsorption process on the Pt(111) surface, also a pseudocapacitive process. On the
23
24
25 other hand, the normalized current between 0.4 and 0.8 V decreases with increasing
26
27
28 scan rate (Figure 2C) because it includes contributions from faradaic and
29
30
31 pseudocapacitive processes. The normalized CVs for 20 and 40 V s⁻¹ overlap,
32
33
34 indicating that above 20 V s⁻¹ the faradaic contribution to the voltammogram is
35
36
37 negligible, and the current recorded between 0.4 and 0.8 V corresponds exclusively to
38
39
40 the adsorption of formate. As can be seen when the CVs at low scan rates (Figure 2E)
41
42
43 are compared with those at 20 or 40 V s⁻¹ (Figs. 2A and C), the onset of the oxidation is
44
45
46 seen to coincide with the onset of formate adsorption and the inhibition of the oxidation
47
48
49 at high potentials occurs when the formate adlayer is just over 50% complete.
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4 Moreover, the small wave observed at high scan rates in the negative scan direction at
5
6
7 ca. 0.6 V, which is probably associated to changes in the formate adlayer, also has an
8
9
10 effect in the oxidation current, as indicated by a sharp increase in the current at low
11
12
13 scan rates at exactly the same potential. A similar effect has been observed during the
14
15
16 oxidation of formic acid on Au(111)³⁰ and was attributed to a disorder-order transition
17
18
19 within the formate adlayer at high coverage, as confirmed recently by comparing the
20
21
22 behavior of formate with that of unreactive acetate on Au(111) electrodes.³¹ As far as
23
24
25 we know this is the first report of this phase transition in the formate adlayer also taking
26
27
28 place on Pt(111) electrodes, although this process can also be identified in the recently-
29
30
31 reported CVs of Pt(111) in very concentrated solutions of perchloric acid containing
32
33
34 formic acid.³²

9

10
11 The same strategy can be used with Pt(100), although the high currents recorded for
12
13 the direct oxidation may impede the observation of the adsorption process. As can be
14
15 seen in Figure 2B and D, the qualitative evolution of the voltammogram is the same as
16
17 that of Pt(111), however, faradaic currents are still not negligible for 30 V s⁻¹. For this
18
19 scan rate, the voltammogram is already distorted due to the fraction of the total IR drop
20
21 that cannot be compensated. In spite of that, the voltammetric profile of the Pt(100)
22
23 electrode measured at 20 V s⁻¹, especially in the negative scan direction, already
24
25 resembles that measured for the same electrode in acetic acid solutions.³³ In fact, a
26
27 sharp peak at ca. 0.35 V is observed, which is equivalent to that observed in the same
28
29 conditions in acetic acid solutions, and the shape of the voltammogram below that
30
31 potential is essentially the same as that measured in acetic or sulfuric acid solutions.
32
33
34
35
36
37
38
39
40
41
42
43
44
45
46
47
48
49 Above 0.4 V, the faradaic currents are not negligible at 20 V s⁻¹, distorting the expected
50
51
52
53 shape. Thus, the adsorption behavior of formate on the Pt(100) surface is essentially
54
55
56
57
58
59
60

1
2
3 the same as that observed in acetic acid/acetate solution. The peak at 0.35 V, therefore,
4
5
6
7 corresponds to the competitive adsorption processes of hydrogen and formate. At 0.06
8
9
10 V, the surface is covered by an adsorbed hydrogen monolayer. The desorption of this
11
12
13
14 layer starts at 0.2 V. As hydrogen is desorbed, formate can adsorb on the surface in a
15
16
17 competitive process, which gives rise to the sharp peak at 0.35 V.³³ Finally, the
18
19
20 adsorption process of formate is completed at ca. 0.45 V. Since at 0.85 V bidentate
21
22
23
24 adsorbed formate forms a compact layer on Pt(100), currents are very low, as happens
25
26
27
28 for the Pt(111) surface.
29
30
31

32 It is worth noting that the adsorption process of formate takes place on a much
33
34
35 narrower potential window on Pt(100) than on Pt(111). On the Pt(100) electrode, it
36
37
38 starts around 0.25-0.3 V, and it is completed at 0.45-0.5 V, whereas for the Pt(111)
39
40
41
42 surface, the adsorption region spans between 0.3 and 0.7 V. This difference in the
43
44
45
46 adsorption behavior has its effect in the current corresponding to the direct oxidation of
47
48
49 formic acid. On the Pt(100) surface, the process is faster leading to a sharp current
50
51
52
53 increase in the region below 0.4 V. Similarly, as the completion of the formate layer is
54
55
56
57
58
59
60

1
2
3 attained at lower potentials, the decay above 0.5 V is also steeper. On the other hand,
4
5
6
7 the formate adsorption process on Pt(111) occurs over a wider potential region, and the
8
9
10 changes in the formic-acid oxidation current are therefore more gradual.
11
12
13

14
15 DFT calculations indicate that the adsorption energy of formate (in both
16
17
18 configurations, bidentate and monodentate) on both surfaces is very similar and,
19
20
21 therefore, the differences described above must be due to the competition between
22
23
24 formate and hydrogen for the adsorption sites on Pt(100).²¹ In absence of adsorbed
25
26
27 hydrogen, the onset of formate adsorption on Pt(100) should have occurred around its
28
29
30 potential of zero free charge (pzfc). The experimental value of the pzfc of Pt(100) is not
31
32
33 available. However, it can be estimated from that of the Pt(111) electrode (0.34 V)³⁴⁻³⁵
34
35
36 and the difference between the work functions of Pt(100) and Pt(111) (ca. 0.1 eV).³⁶
37
38
39 Thus, the onset for adsorption, in absence of adsorbed hydrogen, would have occurred
40
41
42 around 0.25 V, and probably the region where formate coverage changes are recorded
43
44
45 would have also spanned ca. 0.4 V, as with Pt(111) (on which surface formate
46
47
48
49
50 adsorption indeed starts around the pzfc when, coincidentally, desorption of hydrogen is
51
52
53
54
55
56
57
58
59
60

1
2
3 nearly complete). However, due to the presence of adsorbed hydrogen, adsorption of
4
5
6
7 formate on Pt(100) only occurs once some hydrogen has been already desorbed. As
8
9
10 soon as hydrogen is displaced from the surface, the formate coverage should reach its
11
12
13 equilibrium values, and a fast change in coverage is observed. Thus, the number of
14
15
16
17 formate species adsorbing on the surface as the potential changes is higher on the
18
19
20 Pt(100) surface, which implies a higher possibility of adsorbing in the monodentate
21
22
23 configuration and higher currents.
24
25
26
27
28

29 Figure 3A shows CVs of a Pt(111) electrode in 0.1 M HClO₄ with different formic acid
30
31 concentrations (the same data with the complete set of studied concentrations is shown
32
33 in Figure S1A). In all cases, a HMRDE configuration has been used to avoid problems
34
35 arising from transport limitations when low formic acid concentrations are used. For
36
37 clarity, only the negative scan direction is shown. The observed behavior agrees with
38
39 the proposed mechanism. As expected, the onset shifts to lower potential values and
40
41
42
43 higher currents are measured as the formic acid concentration increases from 0.005 to
44
45
46
47
48
49
50
51
52
53 2 M. However, the increase in current is lower than expected: a three orders of
54
55
56
57
58
59
60

1
2
3 magnitude increase in the concentration (from 0.001 to 1 M) leads to just a roughly 3-
4
5
6
7 fold increase in the currents at the maximum (from 1.9 to 6 mA cm⁻²), clearly indicating
8
9
10 the presence of a limitation in the kinetics of the reaction.

Figure 3. Evolution of the voltammetric profile of the Pt(111) (A) and Pt(100) (B) electrodes in a HMRD configuration with increasing formic acid concentration in 0.1 M HClO_4 . Scan rate: 50 mV s^{-1} ; rotation rate: 1600 rpm.

Figure 3B (and S1B) shows the evolution of the CV of a Pt(100) electrode as the formic acid concentration increases from 0.005 M to 2 M (0.005 M formic acid was

1
2
3
4 chosen as lower concentration because, below this value, a significant part of the
5
6
7 voltammograms already shows a diffusion-controlled behavior). The effects of
8
9
10 increasing the concentration of formic acid on the voltammogram differ from those
11
12
13 observed with Pt(111) electrodes (Figure 3A), showing a more complex behavior. In the
14
15
16 region between 0.85 and 0.5 V, the oxidation onset and the current maximum shift to
17
18
19 lower potential values as the concentration increases, as expected if the current in this
20
21
22 region is related to the creation of free sites in the bidentate formate adlayer to allow for
23
24
25 the adsorption of the active intermediate (as the concentration increases, the desorption
26
27
28 in the negative scan direction starts at more negative potential values). On the other
29
30
31 hand, currents at potentials below 0.5 V follow a different trend: (i) peak currents are
32
33
34 constant between 0.01 and 0.05 M and then decrease as the concentration increases;
35
36
37
38 (ii) the currents between 0.4 and 0.3 V first increase with increasing concentration
39
40
41 between 0.005 and 0.25 M, but decrease above 0.25 M (inset in Figure 3B). This
42
43
44
45 behavior clearly reveals some important kinetic limitation for the reaction as well as the
46
47
48 effects of CO poisoning on the voltammogram, because the rate of formation of
49
50
51 adsorbed CO also increases with increasing concentration (see below), affecting the
52
53
54
55
56
57
58
59
60

1
2
3 final shape of the voltammogram. This latter effect is not observed on the Pt(111)
4
5
6
7 surface, because the rate of the CO poisoning is negligible for all the studied
8
9
10 concentrations (positive and negative scan directions of the voltammetric profile almost
11
12
13 overlap completely for all concentrations, as shown, e.g., in Figure 1A and 2E for the
14
15
16 particular cases of 0.05 M and 0.01 M HCOOH, respectively).
17
18
19

20
21
22 In order to properly analyze these differences in the behavior of Pt(111) and Pt(100),
23
24
25 the rate of the direct path needs to be measured. For the Pt(111) electrode, during the
26
27
28 voltammetric scan at 50 mV s^{-1} , the formation of CO through the dehydration reaction of
29
30
31 formic acid is negligible, and thus, the measured currents correspond to the direct
32
33
34 oxidation path. On the other hand, on the Pt(100) surface, CO formation rate is
35
36
37 significant, especially below 0.5 V.²⁸ Thus, the measured currents in the voltammogram
38
39
40 correspond to a surface which is partially blocked by CO. In order to obtain the true
41
42
43 activity of a free surface, pulsed experiments were performed.^{28, 37} During the
44
45
46 conditioning pulse at potentials above 0.8 V, CO is fully oxidized. After 1 second at this
47
48
49
50 potential, the potential is stepped to the desired potential, and the oxidation current
51
52
53
54
55
56
57
58
59
60

1
2
3 transient is recorded (Figure 4). The decay in the transient reflects the progressive
4
5
6 increase of the CO coverage, whereas the initial current at $t=0$ would be the current
7
8
9 measured in the absence of CO. Since this value is not directly measurable, because of
10
11
12 double layer charging at short times, a kinetic model for the reaction needs to be used
13
14
15 to fit the transients.²⁸ The kinetic model employed here is the same one used
16
17
18 previously,²⁸ in which the current measured for the oxidation of formic acid in the
19
20
21 potential region where adsorbed CO cannot be oxidized is directly proportional to the
22
23
24 fraction of the surface not covered by CO:
25
26
27
28
29
30
31

$$j = j_{\theta=0}(1 - \theta_{\text{CO}}) \quad (4)$$

32
33
34
35
36 where $j_{\theta=0}$ is the current at $t = 0$ when $\theta_{\text{CO}} = 0$ (with θ_{CO} the relative coverage by CO).
37
38
39

40 The overall reaction for the formation of adsorbed CO can be described as:
41
42
43

44
45
46 where p corresponds to the number of free Pt sites required. The rate of formation of
47
48
49

50
51 CO_{ad} will therefore be given by:
52
53
54

$$\frac{d\theta_{\text{CO}}}{dt} = k_{\text{ads}}(1 - \theta_{\text{CO}})^p \quad (6)$$

1
2
3
4 where k_{ads} is the apparent rate constant for the dehydration reaction (see below for a
5
6
7 discussion of the mechanism of the dehydration reaction and the meaning of k_{ads}).
8
9

10 Integration of Eq (6) leads to the following expression for θ_{CO} :
11
12
13

$$\theta_{\text{CO}} = 1 - \left(\frac{1}{1 + k_{\text{ads}}t(p-1)} \right)^{\frac{1}{p-1}} \quad (7)$$

14
15
16
17
18 for $p \neq 1$. For $p = 1$, an exponential decay is obtained,²⁷ but as will be shown below, this
19
20

21 is not the case for the present experimental results. The substitution of Eq. (6) into Eq.
22
23

24
25 (4) yields:
26
27

$$j = j_{\theta=0} \left(\frac{1}{1 + k_{\text{ads}}t(p-1)} \right)^{\frac{1}{p-1}} \quad (8)$$

28
29
30
31
32
33 Eq. (8) is able to reproduce the experimental results at $E < 0.6$ V, and allows obtaining
34
35
36 $j_{\theta=0}$ and k_{ads} , the best fittings corresponding to values of p around 2 (as we will see
37
38
39
40 below, this is in excellent agreement with the experimental determination of the
41
42
43 minimum atomic ensemble required for the dehydration of HCOOH on Pt³⁸⁻³⁹). At $E >$
44
45
46
47 0.6 V the current transients are constant because no formation of adsorbed CO takes
48
49
50
51 place. Accordingly, the current measured in the transient is a direct measure of the rate
52
53
54 of CO₂ formation along the direct path.
55
56
57
58
59
60

Figure 4. Transients measured for the pulsed voltammetry at different potentials for the Pt(100) electrode in 0.1 M HClO₄ + 0.01 M HCOOH.

Figure 5 shows the values of $j_{t=0}$ on the Pt(100) electrode for different concentrations of formic acid (Figure S2 shows the same data for all the studied concentrations). For the lowest concentration (0.005 M), the magnitude of $j_{t=0}$ is nearly constant between 0.42 and 0.57 V, a clear indication that in this region and for this concentration, the rate of the reaction is limited by the diffusion of formic acid molecules to the surface. On the other hand, for the range of concentrations between 0.1 and 0.01 M, the values of $j_{t=0}$ around the maximum are nearly independent of the concentration, within the error of the

1
2
3 measurements. In this range of concentrations, the only significant change is the slight
4
5
6 displacement of the onset to lower potential values. It should be noted that the onset of
7
8 the reaction coincides with that of formate adsorption on this electrode, as described
9
10 above, which expectedly shifts negatively with increasing concentration of formic acid.
11
12
13
14
15
16
17 For the higher concentrations, the current decreases with increasing concentration.

54
55
56
57
58
59
60

1
2
3 The almost identical values of $j_{t=0}$ around the maximum for $[\text{HCOOH}] < 0.1 \text{ M}$ suggest
4
5
6
7 that the reaction rate for the Pt(100) electrode in this potential region is almost
8
9
10 independent of the concentration of formic acid in solution. As in any heterogeneous
11
12
13 catalyzed reaction, the formation of the active intermediate requires a solution species,
14
15
16 formate in this case, and a surface site. The independence of the rate on the
17
18
19 concentration implies that the surface site is the limiting reactant for the kinetics. The
20
21
22 activity at a given potential must then be controlled by the residence time of the active
23
24
25 intermediate on the surface, that is, the turnover rate of the site. Thus, all the available
26
27
28 sites for the reaction are occupied by the active intermediate, provided that diffusion
29
30
31 suffices to maintain its coverage, that is for $[\text{HOOH}] > 0.005 \text{ M}$. The time elapsed
32
33
34
35 between adsorption of formate and its transformation to CO_2 , will determine the reaction
36
37
38 rate at a given potential.
39
40
41
42
43
44

45 The behavior for the Pt(111) electrode is different, displaying a clear increase of the
46
47
48 current with increasing concentration at all concentrations and at all potentials. In order
49
50
51 to discard whether these difference is due to a different reaction mechanism, the
52
53
54 reaction order for HCOOH was determined for both surfaces, by plotting either the
55
56
57
58
59
60

1
2
3
4 current density in the CV at constant potential (Pt(111) electrode) or $j_{E=0}$ at constant
5
6
7 potential (Pt(100) surface) vs. the HCOOH concentration in a double logarithmic plot
8
9
10 (Figure 6). The selected potentials were chosen close to the onset of the reaction
11
12
13 because, in this region, the formate coverage is low and therefore the number of free
14
15
16 sites is still large, and the reaction rate increases with potential for both Pt(100) and
17
18
19 Pt(111). As can be seen in Figure 6, for Pt(100) a linear plot is observed for
20
21
22 concentrations lower than 0.5 M. At higher concentrations, other effects are playing a
23
24
25 role in the activity. The slopes of the double logarithmic plots in the linear region are ca.
26
27
28 0.6 at 0.300 and 0.325 V. At $E = 0.350$ V, the slope is lower because this potential is
29
30
31 closer to the maximum current, and thus the reaction rate is controlled by the coverage
32
33
34 of the adsorbed species. For Pt(111) a similar slope of ca. 0.66 is obtained in all cases.
35
36
37 For this electrode and at $E = 0.300$ V, the points at the lowest concentrations deviate
38
39
40 from linearity because of the errors in measuring the very small currents registered at
41
42
43 these concentrations. For $E = 0.375$ V and $[\text{HCOOH}] > 0.1$ M, a deviation from linearity
44
45
46 is observed because currents are reaching the peak values and they are no longer in
47
48
49 the ascending branch of the voltammogram, but rather on the plateau region. The very
50
51
52
53
54
55
56
57
58
59
60

1
2
3 identical values, within the error of the experiments, of the reaction order for Pt(111) and
4
5
6
7 Pt(100), imply that the mechanism is the same for both electrodes, i.e., the reaction rate
8
9
10 is governed by the ability of the surface to form the active intermediate and the
11
12
13
14 residence time of this adsorbed intermediate to yield CO₂.
15

59
60

Figure 6. Double logarithmic plots of $j_{t=0}$ for Pt(100) and j for Pt(111) electrodes at constant potential vs. the formic acid concentration in 0.1 M HClO_4 .

The effect of the specific adsorption of anions other than formate was examined by using a 0.1 M sulfuric acid solution as supporting electrolyte. In this electrolyte,

1
2
3 adsorbed sulfate is present on the surface in the potential region in which the formic
4
5
6
7 acid oxidation reaction takes place. As can be seen in Figure 7 the qualitative behavior
8
9
10 is the same as that measured in perchloric acid solutions (Figure 3): for Pt(111), the
11
12
13 currents increase and the onset is displaced to more negative potentials as the
14
15
16 concentration increases, whereas for Pt(100) surface, the current is almost independent
17
18
19 of the concentration in the range between 0.01 and 0.1 M and the onset also shifts to
20
21
22 lower potentials with increasing concentration, but only up to 0.25 M. This implies that,
23
24
25 in the presence of an adsorbed species that induces the positioning of formate in the
26
27
28 right configuration, the current depends on the interaction of formate with the surface. In
29
30
31 fact, as can be seen in Figures S3 and S4, where voltammograms for the same formic
32
33
34 acid concentration in both electrolytes are compared, the onset of the reaction is slightly
35
36
37 lower in sulfuric acid solutions. Moreover, currents for the Pt(100) electrode in sulfuric
38
39
40 acid are higher than in perchloric, whereas for the Pt(111) surface, currents are similar
41
42
43 except for the lowest concentration. All these results reinforce the idea that the driving
44
45
46 force for the reaction is the nature of the interaction between formate and the surface,
47
48
49 which is potential dependent.

7 **3.2. Adsorbed formate in the indirect path.** The dual-path mechanism of formic acid
8
9
10 oxidation requires that there must be a last intermediate common to both paths. We will
11
12
13 provide here additional evidence showing that, as has been previously suggested,²³⁻²⁴
14
15
16 adsorbed monodentate formate is this last common intermediate. According to this
17
18
19 hypothesis, in the indirect path leading to adsorbed CO, Reaction 2 would be followed
20
21
22 by the reduction of monodentate adsorbed formate:
23
24
25

26
27
28
29
30 which would be the rate determining step in the Pt-catalyzed dehydration of formic acid.
31
32
33

34 The rate of formation of adsorbed CO would therefore be:

$$\frac{d\theta_{\text{CO}}}{dt} = k^0 \exp\left(\frac{-(1-\beta)F\eta}{RT}\right) c_{\text{H}^+} \theta_{\text{formate}} (1 - \theta_{\text{CO}})^p \quad (9)$$

35
36
37
38
39
40 where k^0 and β are the standard rate constant and the symmetry factor of Reaction 8,
41
42
43 respectively, η is the overpotential (measured with respect to the standard potential of
44
45
46 Reaction 8), c_{H^+} is the proton concentration and R and T have their usual meaning. At
47
48
49 constant pH and defining $k^\# = k^0 c_{\text{H}^+}$ Equation 9 is identical to Equation 5, with $k_{\text{ads}} = k^\#$
50
51
52
53
54 $\exp\left(\frac{-(1-\beta)F\eta}{RT}\right) \theta_{\text{formate}}$.
55
56
57
58
59
60

1
2
3
4 As described above, in the case of Pt(100) k_{ads} can easily be obtained from a fit of the
5
6
7 current transients in Fig. 4 to Equation 7. The fact that the best fits are obtained for $\rho \approx$
8
9
10 2, suggesting that two Pt free adsorption sites are required in addition to that occupied
11
12
13 by adsorbed monodentate formate, is in excellent agreement with the well-established
14
15
16 fact that a minimum atomic ensemble consisting of three contiguous Pt atoms is
17
18
19 required for the dehydration of formic acid.³⁸⁻³⁹
20
21
22
23

24 Figure 8 shows a plot of k_{ads} on Pt(100) as a function of the electrode potential. At the
25
26
27 initial stages of the reaction, $\theta_{\text{CO}} = 0$, and, therefore, $\frac{d\theta_{\text{CO}}}{dt} = k^{\#} \exp\left(\frac{-\beta F \eta}{RT}\right) \theta_{\text{formate}} = k_{\text{ads}}$,
28
29
30
31 *i.e.*, k_{ads} corresponds to the rate of the dehydration reaction at $t = 0$. The bell-shaped
32
33
34 plots in Figure 6 are in agreement with previously reported results,²⁷⁻²⁸ as well as with
35
36
37 the reaction mechanism proposed in refs ^{7-8, 23-24}, in which monodentate adsorbed
38
39
40 formate is the precursor of adsorbed CO. The fact that no CO forms at all below 0.2 V is
41
42
43 also consistent with this mechanism because, as has been shown above, at more
44
45
46 negative potentials adsorption of formate is blocked by hydrogen adsorption. As
47
48
49 discussed in ⁸, for this mechanism, and assuming that the adsorption of formate can be
50
51
52
53
54
55
56
57
58
59
60

described by a Langmuir isotherm, the potential at which the rate of dehydration is maximum (E_{\max}) must shift negatively with increasing concentration of formic acid according to:

$$E_{\max} = \left\{ 2.3 \frac{RT}{F} \left[\log \left(\frac{\beta}{1-\beta} \right) - \frac{1}{2} \log K_L \right] + E_{\text{pzc}} \right\} - 2.3 \frac{RT}{F} \log c_{\text{HCOOH}} \quad (10)$$

where K_L is the Langmuir constant of the formate adsorption equilibrium, E_{pzc} is the potential of zero charge and c_{HCOOH} is the concentration of formic acid.

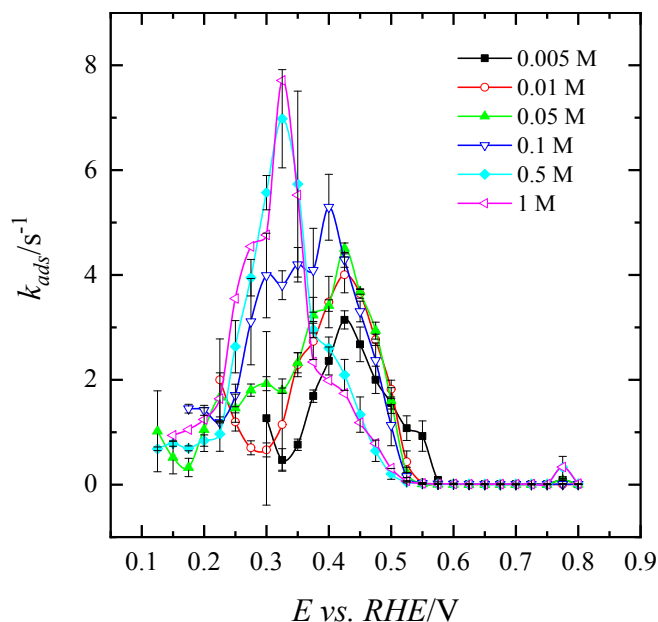

Figure 8. k_{ads} vs. E measured for the transients recorded during the pulsed voltammetry in 0.1 M HClO_4 for different formic acid concentrations.

1
2
3 Similarly, as also predicted in ⁸, if the adsorption of formate follows a Langmuir
4 isotherm, the rate of formation of adsorbed CO when $\theta_{\text{CO}} = 0$, *i.e.*, k_{ads} , at the potential
5
6
7 at which it is maximum, $k_{\text{ads}}^{\text{max}}$, must increase with increasing concentration of formic acid
8
9
10 according to:
11
12
13
14
15
16

$$\log k_{\text{ads}}^{\text{max}} = A + (1 - \beta) \log c_{\text{HCOOH}} \quad (11)$$

17
18 with $A = \left\{ \log \frac{k^0}{2} - (1 - \beta) \left[\frac{(E_{\text{pzc}} - E_{\text{eq}})}{2.3RT} + [\log \beta - \log (1 - \beta) - \log \sqrt{K_L}] \right] \right\}$. (Please note that
19
20
21
22
23
24 there is a typographical error in Eq. 30 of ⁸ which has been corrected here.)
25
26

27 A semilogarithmic plot of E_{max} vs. c_{HCOOH} is shown on Figure 6B (black squares and
28
29
30 dashed black line), according to which the potential at which the rate of dehydration of
31
32
33 formic acid to yield adsorbed CO on Pt is maximum shifts negatively by 49 mV every
34
35
36
37 tenfold increase of the formic acid concentration. This is smaller than the -59 mV shift
38
39
40
41 predicted by Eq. 10. However, Eq. 10 assumes that the adsorption of formate is
42
43
44
45 Langmuirian, which implies that the maximum corresponds always to the same formate
46
47
48 coverage. This does not take into account the possibility of either repulsive or attractive
49
50
51 interactions between neighboring adsorbed formate molecules at intermediate to high
52
53
54 coverage, and, most importantly, does not take into account the overlap on Pt(100)
55
56
57
58
59
60

1
2
3 between hydrogen and formate adsorption. As discussed in the previous section, this
4
5
6
7 overlap affects the formate adsorption isotherm exactly in the potential region where the
8
9
10 maximum rate of dehydration happens. The consequence is that a potential more
11
12
13 positive than expected in the absence of a competing adsorbate (hydrogen) will be
14
15
16 required to achieve the formate coverage corresponding to the maximum rate of
17
18
19 dehydration (which, furthermore, will not anymore be the same at all a_{HCOOH}), and the
20
21
22 shift of E_{max} with a_{HCOOH} will be smaller than expected, as indeed observed.
23
24
25
26
27

28 A double logarithmic plot of $k_{\text{ads}}^{\text{max}}$ vs. a_{HCOOH} is also included in Figure 9 (red circles
29
30
31 and dashed red line). The slope of the plot, 0.16 is considerably smaller than expected
32
33
34 from Eq. 11 if $\beta = 0.5$, which is in apparent contradiction with a previous determination
35
36
37 of the Tafel slope of Reaction 8 of 128 mV.⁷ However, like Eq. 10, Eq. 11 is only correct
38
39
40 if the adsorption of formate is Langmuirian and fails to take into account the competition
41
42
43 for the adsorption sites between hydrogen and formate in the potential region where
44
45
46 E_{max} occurs. In particular, whereas a Langmuirian adsorption implies that the formate
47
48
49 coverage at E_{max} will always be the same whatever the concentration of formic acid, the
50
51
52 shift of E_{max} into the hydrogen adsorption region when a_{HCOOH} increases will result in a
53
54
55
56
57
58
59
60

1
2
3 lower formate coverage at E_{\max} and, therefore, in a dehydration rate lower than
4
5
6
7 expected from Eq. 11, thus explaining a gradient in Figure 6B (red line) smaller than
8
9
10 expected.

Figure 9. Plot of the potential for the maximum k_{ads} and its value vs. concentration.

34
35
36
37
38
39
40
41 We would like to finish this section by highlighting that the potential dependence of the
42
43 rate of formation of adsorbed CO from the dehydration of formic acid (Figure 8) is only
44
45
46 consistent with a mechanism in which an oxidative electroadsorption step is followed by
47
48
49 a rate-determining reduction step. The only possible alternative to the sequence formate
50
51
52 adsorption – formate reduction is the fast adsorption of $-\text{COOH}$ followed by its rate-
53
54
55
56
57
58
59
60

1
2
3 determining reduction, but this would imply the very unlikely fast activation of the C-H
4
5
6
7 bond in formic acid. This, together with the reasonable agreement with the predictions
8
9
10 made in ⁸ of the observed dependence on the concentration of both the potential at
11
12
13 which the rate of dehydration is maximum and of the rate at that potential confirm that
14
15
16
17 monodentate adsorbed formate is also the intermediate in the indirect path.
18
19
20
21

22 CONCLUSIONS

23
24
25

26 A thorough analysis of the dependence of the voltammetric profile of Pt(111) and
27
28
29 Pt(100) electrodes in solutions containing formic acid on the scan rate and on the formic
30
31
32 acid concentration, as well as of the current transients in pulsed voltammetry
33
34
35
36 experiments, has allowed us to provide evidence that an adsorbed-formate species is
37
38
39 the reactive intermediate both in the direct and the indirect path of the formic acid
40
41
42
43 oxidation reaction. As bidentate adsorbed formate has been shown to be too unreactive,
44
45
46
47 monodentate adsorbed formate must be the reactive species, the last common
48
49
50
51 intermediate in the dual reaction path. After the oxidative electroadsorption of
52
53
54
55
56
57
58
59
60

1
2
3 monodentate formate, and depending on the potential, it can either be reduced to yield
4
5
6
7 adsorbed CO (a catalytic poison) or oxidized to the final product, CO₂.
8
9

10
11 In the direct path, although unreactive, bidentate adsorbed formate is not just an
12
13
14
15 innocent spectator. At low to medium coverages, the presence of neighboring bidentate
16
17
18 formate helps stabilize the monodentate reactive species, which might explain the
19
20
21
22 second order of the reaction with respect to bidentate formate reported in previous
23
24
25 work.^{8, 28} Other adsorbed species, like, e.g., specifically adsorbed sulfate, can also play
26
27
28 this role. However, at coverages above 50% of the maximum, the blocking effect of
29
30
31
32 bidentate formate overcomes its effect on the stabilization of monodentate formate, and
33
34
35
36 increasing its coverage leads to the inactivation of the electrode surface. At very high
37
38
39 coverages, a spike in the cyclic voltammograms suggests a disorder-order phase
40
41
42
43 transition within the formate adlayer that leads to a further deactivation of the surface. A
44
45
46 similar transition has been found previously on Au(111) electrodes³⁰ but, as far as we
47
48
49 know, had never been reported for Pt(111) before.
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4 Since the specific adsorption of formate starts around the pzfc, neither the dehydration
5
6
7 to adsorbed CO nor the oxidation to CO₂ can occur at a potential more negative than
8
9
10 the pzfc. This leads to differences between Pt(111) and Pt(100) regarding the increase
11
12
13 in the reaction rate along the direct path with increasingly positive potential, as well as
14
15
16 regarding their activity for the formation of the catalytic poison. In the case of the
17
18
19 Pt(100) surface, the pzfc occurs in a potential region in which the surface is covered by
20
21
22 adsorbed hydrogen and prevents the adsorption of formate, whereas in the case of
23
24
25 Pt(111), most of the hydrogen has desorbed at the pzfc. The consequence is that, in the
26
27
28 case of Pt(100), formate immediately replaces hydrogen as soon as the latter desorbs,
29
30
31 leading to a sharp rise in formate coverage and therefore in the current for the direct
32
33
34 oxidation of formic acid. On the contrary, on Pt(111) both the formate coverage and the
35
36
37 current increase gradually with increasing potential.
38
39
40
41
42
43
44
45

46 Regarding the formation of adsorbed CO, due to the more negative pzfc of Pt(100), a
47
48
49 sufficiently high coverage of adsorbed formate can be reached at a relatively negative
50
51
52 potential, leading to a high rate of reduction of adsorbed formate and a high rate of CO
53
54
55
56
57
58
59
60

1
2
3 poisoning. On the contrary, on Pt(111), a high coverage of adsorbed formate can only
4
5
6
7 be reached at relatively positive potentials, at which the reduction of adsorbed formate
8
9
10 to adsorbed CO is slow, thus explaining the slow poisoning by CO of Pt(111) electrodes
11
12
13
14 in the absence of defects. On Pt(100), the dependence of the rate of formation of
15
16
17 adsorbed CO on the potential shows a bell shape. The potential at which the rate of
18
19
20
21 formation is maximum decreases and the rate at the maximum increases with
22
23
24 increasing concentration of formic acid, in good agreement with previous predictions in
25
26
27
28 which adsorbed CO is formed by the adsorption of formate followed by the reduction of
29
30
31 adsorbed formate.
32
33
34
35

36 The presented results point out that monodentate adsorbed formate is the last common
37
38
39 intermediate for both direct and indirect pathways on Pt electrodes, and this conclusion
40
41
42
43 can be extrapolated to other metals. Depending on the energetics of each pathway on
44
45
46 the different electrodes, their reaction rates would be different, giving different
47
48
49
50 behaviour. For Pt electrodes, the reaction rates for the intermediate pathway on Pt(111)
51
52
53 are negligible, because a sufficiently high formate coverage happens only at potentials
54
55
56
57
58
59
60

1
2
3 too positive for the step leading to the formation of CO through reduction of the
4
5
6
7 monodentate adsorbed formate to be fast, whereas on Pt(100) there is a potential
8
9
10 window where this reaction is possible at higher formate coverage. Evidence that
11
12
13 oxidation of formic acid also proceeds through adsorbed monodentate formate on other
14
15
16 metal surfaces has been provided in the case of Au^{30-31, 40-41} and Pd⁴² electrodes, as
17
18
19 well as for several metal surfaces at the solid-gas interface.⁴³⁻⁴⁸ Cyclic voltammetry and
20
21
22 DFT calculations suggested that the stabilization of monodentate adsorbed formate can
23
24
25
26
27 take place by the presence of adatoms or other adsorbed species on the Pt surface,²¹
28
29
30
31 and a similar effect has been proposed recently for Bi-modified Pd nanoparticles also
32
33
34 supported by theoretical calculations.⁴⁹ Thus, the mechanism presented here can be
35
36
37
38 considered as general, the differences between different surfaces being due to the ratio
39
40
41
42 between the rate constants for each pathway (as in the case of, *e.g.*, Pd) and/or to a
43
44
45 lower CO adsorption energy (as in the case of Au), both of which will depend on the
46
47
48
49 electronic properties of each specific surface.
