Abstract

The synthesis and characterisation of two homologous series of non-symmetric dimers are reported, the \(1-(4\text{-methoxybiphenyl}-4'\text{-yl})-6-(4\text{-alkylanilinebenzylidene}-4'\text{-oxy})\text{hexanes (MeOB6O}_m, m=1-10)\) and \(1-(4\text{-methoxybiphenyl}-4'\text{-yl})-6-(4\text{-alkyloxyanilinebenzylidene}-4'\text{-oxy})\text{hexanes (MeOB6O}_O m, m=1-9)\). All ten members of the \(\text{MeOB6O}_m\) series exhibit the conventional nematic phase. At lower temperatures the members with \(m=1-7\) formed the twist-bend nematic phase, whereas for \(m=8-10\) smectic behaviour replaced the twist-bend nematic, \(N_{TB}\), phase. All nine members of the \(\text{MeOB6O}_O m\) also show the conventional nematic phase and for \(m=1-3\), a strongly monotropic \(N_{TB}\) phase is also observed. The alkyloxy terminated dimers show the higher values of \(T_{NI}\) and \(T_{N_{TB}}\). For both series, the values of \(T_{NI}\) and \(T_{N_{TB}}\) show a modest alternation and in the same sense as \(m\) is increased. These observations suggest that the spatial uniformity of molecular curvature is important in driving the formation of the \(N_{TB}\) phase. The observation of smectic behaviour is attributed to the molecular inhomogeneity arising from the long terminal alkyl chain driving microphase separation. The transitional behaviour of these series is compared to those of the corresponding cyanobiphenyl-based series and overarching observations discussed.
1. Introduction

The discovery of the twist-bend nematic phase, N_{TB} [1] and its subsequent verification [2, 3] triggered significant and global research interest. First predicted some thirty years earlier by Meyer [4] and later independently by Dozov [5], the N_{TB} phase is fascinating for a number of reasons but perhaps most so for the observation of spontaneous chirality in a collection of achiral molecules. Indeed, the N_{TB} phase provided the first example of spontaneous chiral symmetry breaking in a fluid with no spatial ordering. Dozov’s prediction of the N_{TB} phase was underpinned by the assumption that bent molecules have a strong natural tendency to pack into bent structures [5]. However, pure uniform bend in space is not allowed, and must be accompanied by other local deformations of the director, namely, splay or twist. In the N_{TB} phase, the directors form a helix and are tilted with respect to the helical axis. The formation of this structural chirality is spontaneous, and so an equal number of the degenerate left- and right-handed helices would be expected. The introduction of intrinsic molecular chirality lifts this degeneracy and the chiral N_{TB} phase is observed [6].

The first assignment of the N_{TB} phase was for the liquid crystal dimer, CB7CB [1]:

![Image of CB7CB molecule]

Liquid crystal dimers consist of molecules containing two mesogenic units connected via a flexible alkyl spacer, and their transitional behaviour is strongly dependent on the length and parity of the spacer [7-9]. This dependence is attributed to how the spacer controls the average molecular shape. Specifically, if an even number of atoms connect the two mesogenic units then the long axes of these moieties are essentially parallel, and the molecule is linear. By contrast, for an odd number of connecting atoms, the mesogenic groups are inclined at some angle with respect to each other, and the molecule is bent. Thus, CB7CB is, on average, a bent molecule, and the observation of the N_{TB} phase may be accounted for within the framework of Dozov’s prediction [5]. Indeed, the vast majority of twist-bend nematogens may be described as odd-membered liquid crystal dimers (see for example [10-28]) although other structures including hydrogen-bonded materials [29-33], higher oligomers [34-40], polymers [41] and semi-rigid bent-core materials [42] have also been shown to exhibit the N_{TB} phase. In each of these classes of material, however, it is widely accepted that the stability of the N_{TB} phase is strongly dependent on molecular shape, and specifically, molecular curvature. This view is in accord with predictions made using a generalised Maier-Saupe theory for which the nematic-twist-bend nematic transition temperature is shown to be highly sensitive to the bend angle for V-shaped molecules [43, 44]. These bent materials have been shown to have considerable application potential [39, 45-47].
Dozov not only predicted that bent molecules may exhibit the N$_{TB}$ phase but also that they may show heliconical smectic phases [5]. We recently reported the discovery of these twist-bend smectic phases for odd-membered liquid crystal dimers [48, 49]. In order to begin to establish the relationship between molecular structure and the formation of these new twist-bend phases, we investigated the transitional behaviour of two series of non-symmetric liquid crystal dimers in which the length of a terminal chain was varied, the 1-(4-cyanobiphenyl-4'-yl)-6-(4-alkyloxyanilinebenzylidene-4'-oxy)hexanes (CB6O.Om) [23],

\[
\begin{align*}
\text{NC} & - \text{Ph} - (\text{CH}_2)_6 \text{O} - \text{Ph} - \text{N} - \text{Ph} - \text{OC}_n \text{H}_{2n+1} \\
\end{align*}
\]

and the structurally similar 1-(4-cyanobiphenyl-4'-yl)-6-(4-alkylanilinebenzylidene-4'-oxy)hexanes (CB6O.m) [50],

\[
\begin{align*}
\text{NC} & - \text{Ph} - (\text{CH}_2)_6 \text{O} - \text{Ph} - \text{N} - \text{Ph} - \text{C}_m \text{H}_{2m+1} \\
\end{align*}
\]

For the CB6O.Om series, N and N$_{TB}$ phases were observed for all the homologues prepared \((m=1-10)\) whereas smectic behaviour was seen only for \(m=3-5\) [23]. All ten members of the CB6O.m \((m=1-10)\) series also showed N and N$_{TB}$ phases but only the decyl homologue exhibits smectic behaviour [49, 50]. To better understand the formation of smectic phases by bent non-symmetric dimers, we report here the synthesis and characterisation of the analogous materials but with a methoxy terminal substituent, the 1-(4-methoxybiphenyl-4'-yl)-6-(4-alkylanilinebenzylidene-4'-oxy)hexanes (MeOB6O.m), and 1-(4-methoxybiphenyl-4'-yl)-6-(4-alkyloxyanilinebenzylidene-4'-oxy)hexanes (MeOB6O.Om),

\[
\begin{align*}
\text{MeO} & - \text{Ph} - (\text{CH}_2)_6 \text{O} - \text{Ph} - \text{N} - \text{Ph} - \text{X} \\
\text{MeOB6O.m} : X = \text{C}_m \text{H}_{2m+1} & \quad m = 1-10 \\
\text{MeOB6O.Om} : X = \text{OC}_m \text{H}_{2m+1} & \quad m = 1-9 \\
\end{align*}
\]

A comparison of the properties of these four series will allow us to comment on the importance of the polarity of the terminal group in stabilising the N$_{TB}$ and smectic phases, and on the role played by the interaction between the unlike mesogenic groups in driving the formation of these phases.
2. Experimental

2.1. Materials

The synthetic routes used to obtain the MeOB6O\(_m\) and MeOB6O\(_{Om}\) series are shown in Scheme 1. Full synthetic descriptions and structural characterisation data for all the final products and their intermediates are given in the associated supplementary information.

![Scheme 1. The syntheses of the MeOB6O\(_m\) and MeOB6O\(_{Om}\) series.](image)

2.2. Thermal characterisation

The phase behaviour of the compounds was studied by differential scanning calorimetry (DSC) using a Mettler-Toledo DSC820 fitted with an intracooler and calibrated using indium and zinc as standards. The thermograms were obtained during heating and cooling scans at 10°C min\(^{-1}\), under a nitrogen atmosphere. All samples were measured in duplicate. Transition temperatures and associated
enthalpy changes were extracted from the second-heating trace, and those listed are an average for both samples measured. Phase assignments were made by polarised optical microscopy (POM), using an Olympus BH2 microscope equipped with a Linkam TMHS 600 heating stage.

2.3 Molecular modelling

The geometric parameters and electronic properties of the dimers were calculated using quantum mechanical density functional theory [51]. Geometric optimisation of the dimers with the spacer in the all-trans conformation was performed using Gaussian G09W at the B3LYP/6–31G(d) level of theory. The all-trans conformers were selected for reasons discussed in detail elsewhere [10]. Visualisation of space-filling models of the output post-optimisation was performed using QuteMol [52] and Gaussview 5 was used for the visualisation of electrostatic potential isosurfaces, ball-and-stick models and dipole moments [53]

3. Results and Discussion

3.1. MeOB6O.m series

The transitional properties of the MeOB6O.m series are listed in Table 1. All ten members exhibit a conventional nematic (N) phase identified on the basis of the observation of characteristic optical textures when viewed through the polarised light microscope. Specifically, schlieren textures were seen containing both types of point singularities and which flashed when subjected to mechanical stress, see Figure 1(a). The scaled values of the entropy change associated with the N-isotropic (I) transition are listed in Table 1 and are wholly consistent with this assignment [54, 55]. On cooling isolated droplets of the N phase seen for the homologues with \( m = 1 - 7 \), the schlieren texture changed to give regions of parabolic defects in coexistence with rope-like features, see Figure 1(b). In addition, the transition was accompanied by the cessation of optical flickering associated with the directors in the conventional N phase. In a cell treated for planar alignment, on cooling, the homogenous nematic texture changed to the characteristic striped texture of the NTB phase, see Figure 2. On cooling the nematic phase seen for homologues with \( m = 8 - 10 \), coexisting regions of focal conic fan and homeotropic textures developed suggesting the formation of a smectic A phase, see Figure 3. On further cooling, a schlieren texture containing two- and four-point brush defects developed from the homeotropically aligned regions, suggesting the formation of a tilted smectic phase (Figure 4). Two-brush defects are characteristic of phases in which the mesogenic units are arranged in an anticlinic fashion, suggesting this is the \( \text{SmC}_{\text{A}} \) phase. We cannot rule out the possibility, however, that this is an example of the heliconical \( \text{SmC}_{\text{TB}} \) phase having a distorted clock structure such that the molecular orientations are not fully averaged over the helix and for which a schlieren texture containing two-
and four-point brush defects may be observed [48, 49]. The monotropic nature of these smectic phases prevents their characterisation using resonant X-ray diffraction, and thus the assignment of the lower temperature phase as a $\text{SmC}_A$ phase remains tentative.

*Exotherms associated with crystallisation and the N-I transition overlap.

†Temperatures measured using the polarised light microscope on cooling.
Figure 1. (a) Nematic schlieren (T=102°C) and (b) parabolic defect twist-bend nematic texture (T=75°C) seen for MeOB6O.1.

Figure 2. (a) Homogeneous N texture (T=99°C) and (b) striped N_{TB} texture (T=74°C) observed for MeOB6O.1 in a 3 micron cell treated for planar alignment. The stripes are parallel to the rubbing direction.

Figure 3. Focal conic fan texture in coexistence with regions of homeotropic alignment of the SmA phase seen for MeOB6O.10 at (T = 90 °C).
Figure 4. (a) Nematic schlieren texture (T=95°C), (b) the predominantly homeotropically aligned smectic A phase (T=87°C) and (c) the schlieren texture of the smectic C phase (T=78°C) obtained on cooling MeOB6O.9.

In order to confirm that the smectic A phase observed for homologues with $m=8-10$ was not in fact the N_{TB} phase, a binary phase diagram was constructed for mixtures of MeOB6O.9 and the extensively studied twist bend nematogen, CB7CB [1], see Figure 5. The mixtures were prepared by codissolving preweighed amounts of the dimers in dichloromethane. The solvent was allowed to slowly evaporate at room temperature, and the mixture dried under vacuum at 50 °C overnight. All the mixtures exhibited the conventional nematic phase and complete miscibility of the nematic phase was observed for all compositions. Mixtures containing 36 mol % and greater CB7CB exhibited the N_{TB} phase, see Figure 6, whereas at lower concentrations SmA behaviour is seen and a discontinuity in the phase diagram is apparent. This confirms the smectic phase assignment on increasing $m$.

Figure 5. Phase diagram constructed for binary mixtures of MeOB6O.9 and CB7CB. Triangles represent N-I transitions, squares N_{TB}-N transitions and crosses SmA-N transitions. Melting points have been omitted for the sake of clarity.
Figure 6. The polygonal texture seen for the $N_{TB}$ phase of a binary mixture containing 64 mol% MeOB6O.9 and 36 mol% CB7CB ($T = 72^\circ$C).

The dependence of the transition temperatures on the length of the terminal alkyl chain, $m$, for the MeOB6O.$m$ series is shown in Figure 7. It is immediately apparent that, with the exception of MeOB6O.3, the MeOB6O.$m$ series are all monotropic nematogens. The melting point falls initially on increasing $m$ but tends towards a limiting value as $m$ increases further. The nematic-isotropic transition temperature, $T_{NI}$, tends to decrease on increasing $m$ and superimposed on this is a modest alternation in which odd members show the higher values, and which attenuates on increasing $m$. This is characteristic behaviour for this class of material and may be attributed to the change in shape anisotropy on varying the parity of the terminal chain [56, 57]. Specifically, a methylene group added to an even-membered chain lies more or less parallel to the major molecular axis whereas if added to an odd-membered chain lies at an angle to this axis. Thus, a larger increase in the anisotropic shape of the molecule is evident on forming an odd-membered chain. The underlying decreasing trend in $T_{NI}$ may be accounted for by the dilution of the interactions between the mesogenic units on increasing the length of the terminal chain. The rather small change in $T_{NI}$ of less than 20 $^\circ$C across the whole series is typical for a series of nematogens with values of $T_{NI}$ slightly above about 100$^\circ$C [57]. For series showing higher values of $T_{NI}$, a more pronounced decrease is observed on increasing the terminal alkyl chain length arising from the dilution of the stronger interactions between the mesogenic units. By contrast, for nematogenic series with values of $T_{NI}$ lower than about 100$^\circ$C, there is an underlying increase in $T_{NI}$ on increasing chain length reflecting the enhanced molecular anisotropy associated with increasing the length of the chain. At around 100 $^\circ$C these two effects are more or less balanced and a rather flat $T_{NI}$ line is observed as seen in Figure 7. The twist-bend nematic-nematic transition temperature, $T_{N_{TB}N}$, also exhibits an alternation on increasing $m$ and in the same sense as that seen for $T_{NI}$. Furthermore, $T_{N_{TB}N}$ does not show the same underlying decreasing trend as $T_{NI}$ on increasing $m$ such that increasing $m$ stabilises the $N_{TB}$ relative to the N phase. This
suggests that the effect of the terminal chain length on $T_{N_{TB}N}$ may also be accounted for in terms of the change in molecular shape anisotropy on varying $m$. It is interesting to note, however, that the values of $T_{N_{TB}N}$ for a given parity chain are rather insensitive to increases in chain length. This suggests that the dilution of the interactions between the cores arising from increasing chain length has a smaller effect on the predominantly shape driven $N_{TB}-N$ transition than on the $N-I$ transition. It may appear counter intuitive, therefore, that the sense of the alternation seen for $T_{N_{TB}N}$ and $T_{NI}$ is the same given that molecular curvature is widely held to be a prerequisite for the observation of the $N_{TB}$ phase. Thus, increasing the molecular shape anisotropy increasing $T_{NI}$ might be expected to reduce $T_{N_{TB}N}$ and *vice versa*, so giving an alternation in the opposite sense. It has been shown, however, that for liquid crystal dimers a spatially uniform molecular curvature is required to promote the $N_{TB}$ phase such that the photoisomerization of a twist-bend azobenzene-based nematogen to the bent cis isomer destroys the $N_{TB}$ phase [58]. Similar observations have been made for the dependence of $T_{N_{TB}N}$ and $T_{NI}$ for other liquid crystal dimer series [23, 50]. This suggests that odd-membered chains which greater enhance the anisometric shape of the molecule also maintain the spatial uniformity of the molecular curvature. Smectic behaviour emerges for the longest three members of the MeOB6O$_m$ series and the $N_{TB}$ phase is extinguished. The emergence of smectic behaviour for long terminal chains is in accord with the general observation that for smectic phases to be observed in symmetric or non-symmetric dimers in which the mesogenic units do not show a specific favourable interaction, the combined lengths of the terminal chains has to exceed that of the flexible spacer [56, 59]. It has been suggested that the interaction between the terminal chains and spacer is an unfavourable one and must be offset by a specific favourable interaction between the unlike mesogenic units. If present, such an interaction drives the formation of an intercalated phase providing the combined lengths of the terminal chain is less than or comparable to the spacer length [60, 61]. Otherwise, a monolayer smectic phase is observed providing the combined length of the terminal chains exceeds that of the spacer, driven by the increased molecular inhomogeneity arising from the long terminal alkyl chain.
Figure 7. The dependence of the transition temperatures on the number of carbon atoms, $m$, in the terminal alkyl chain for the MeOB6O.m series. Empty circles indicate melting points, filled circles nematic-isotropic transition temperatures, filled squares twist-bend nematic-nematic transitions, filled diamonds smectic A-nematic transitions and filled triangles smectic C-smectic A transitions.

The transitional properties of the MeOB6O.Om series are listed in Table 2. All nine members exhibit a monotropic, conventional nematic phase. In addition, for $m=1$-3 a strongly monotropic NTB phase is observed. Phases assignments were based on the observation of characteristic optical textures as described earlier. The dependence of the transition temperatures on the length of the terminal alkyl chain length $m$ is shown in Figure 8, and it is apparent that the behaviour observed is similar to that seen in Figure 7 for the MeOB6O.m series. The larger decrease in $T_{NI}$ across the series may be attributed to the higher interaction strength parameters between the mesogenic units which is reflected in the higher values of $T_{NI}$, and the more significant role of the chain in diluting these. We note that even members of this series now show the higher values of $T_{NI}$ and $T_{N_{TB}N}$ because the oxygen atom must be considered part of the chain, and hence an even-membered carbon chain corresponds to an overall odd membered chain. The absence of either NTB or smectic behaviour on increasing $m$ for the MeOB6O.Om series may be attributed to the higher melting points of this series and the difficulty associated with supercooling the monotropic nematic phases.

*Exotherms associated with crystallisation obscured that associated with the N-I transition.

<sup>†</sup>Temperatures measured using the polarised light microscope on cooling.
Figure 8. The dependence of the transition temperatures on the number of carbon atoms, $m$, in the terminal alkyl chain the MeOB6O.O$m$ series. ○ indicates melting points, nematic-isotropic transition temperatures, and twist-bend nematic-nematic transitions.

The melting points of the four series, MeOB6O.$m$, MeOB6O.O$m$, CB6O.$m$, and CB6O.O$m$, are compared in Figure 9. The MeOB6O.O$m$ series shows the highest melting points for all values of $m$. The melting points of the MeOB6O.$m$ dimers are higher than the corresponding members of the CB6O.$m$ series except for the propyl homologues for which CB6O.3 has a marginally higher melting point than MeOB6O.3. For shorter terminal chains, the CB6O.O$m$ dimers show the second highest melting points but these fall quickly as $m$ is increased and for the higher values of $m$ the melting points of the corresponding members of the CB6O.$m$, and CB6O.O$m$ series are very similar and lower than those of the MeOB6O.$m$ series. These data support the general observation that the methoxy group promotes higher melting points than a nitrile terminal group [62-64], and dimers having terminal alkoxy chains have higher melting points than the corresponding alkyl substituted materials [23, 50]. These trends may be attributed to the more efficient packing of the methoxy group and alkoxy chains compared to the nitrile and alkyl chains, respectively, and the enhanced polar interactions between alkoxy chains.
Figure 9. A comparison of the melting points as a function of the length of the terminal chain, $p$, for the MeOB6O.O$m$ (filled circles), MeOB6O.$m$ (empty circles), CB6O.O$m$ (filled squares), and CB6O.$m$ (empty squares) series. For the MeOB6O.$m$ and CB6O.$m$ series, $p=m$ and for the MeOB6O.O$m$ and CB6O.O$m$ series, $p=m+1$.

The nematic-isotropic transition temperatures, $T_{NI}$, of the MeOB6O.O$m$ and MeOB6O.$m$ series are compared in Figure 10. The value of $T_{NI}$ for a given member of the MeOB6O.O$m$ series is higher than that of the corresponding member of the MeOB6O.$m$ series. These differences are greater for shorter chains; for example, $T_{NI}$ for MeOB6O.O1 is 38.1 °C higher than that of MeOB6O.2 whereas for the highest three values of $m$ this difference has fallen to around 23 °C. The values of $T_{NI}$ for the CB6O.O$m$ and CB6O.$m$ series are also shown on Figure 10 and similar behaviour is observed such that $T_{NI}$ for a given member of the CB6O.O$m$ series is higher than that of the corresponding member of the CB6O.$m$ series. The differences in $T_{NI}$ are also similar; for example, $T_{NI}$ for CB6O.O1 is 35 °C higher than that of CB6O.2, and this difference falls to 25 °C when comparing the values of $T_{NI}$ for CB6O.O9 and CB6O.10. The increase in $T_{NI}$ on changing an alkyl to an alkyloxy chain may be attributed to the associated change in the average molecular shape. An alkyloxy chain lies more or less in the plane of the ring to which it is attached whereas an alkyl chain protrudes at an angle, see Figure 11. The greater shape anisotropy of the former accounts for the observed higher values of $T_{NI}$. On increasing chain length, conformational averaging reduces this difference in shape and the differences in $T_{NI}$ between the corresponding alkyloxy and alkyl series become smaller. It is apparent that the cyanobiphenyl-based series show higher values of $T_{NI}$ than their methoxybiphenyl-based counterparts. For smaller values of $m$ this difference is around 10 °C and falls to essentially 0 °C as $m$
is increased. This may be accounted for in terms of the change of shape arising from exchanging a nitrile for a methoxy group [10] and the tendency of cyanobiphenyl units to arrange themselves in an anti-parallel fashion so enhancing structural anisotropy [65]. The convergence of the values of $T_{NI}$ for the two alkyloxy and alkyl series as the length of the terminal chain increases, suggests that the difference in shape may be the more significant of these contributions given that this is reduced as the molecules become larger.

**Figure 11.** The electrostatic potential isosurfaces (top), space filling (middle) and ball-and-stick models showing the molecular dipole moment (not to scale, bottom) of (a) MeOB6O.3 and (b) MeOB6O.02.
Figure 12 compares the dependence of the twist-bend nematic – nematic transition temperature, $T_{N_{TB}N}$, on the length of the terminal chain for the four series. Rather similar behaviour is seen as for $T_{NI}$ in Figure 10. For both sets of dimers, the alkyloxy series shows the higher values of $T_{N_{TB}N}$ although the differences are smaller at around 10 °C and decrease with increasing $m$. Presumably a similar argument holds as described for the effects on $T_{NI}$, and that the alkyloxy chain allows for a more spatially uniform molecular curvature facilitating the local packing of these bent molecules. Changing the terminal substituent from a nitrile to a methoxy group also effects $T_{N_{TB}N}$ in a similar fashion to $T_{NI}$. Thus, for short terminal chains a reduction in $T_{N_{TB}N}$ of around 10 °C is observed and this difference becomes smaller as $m$ is increased. Again, this suggests that the shapes of these dimers become more similar as $m$ is increased, and that the molecular curvature is determined largely by the hexyloxy spacer. Molecular curvature plays a major role in determining the bend elastic constant that drives the formation of the $N_{TB}$ phase [66]. The difference in $N_{TB}$ between these particular series may be attributed, at least in part, to a specific favourable interaction between the cyanobiphenyl and benzylideneaniline moieties which is thought to play an important role in determining the phase behaviour of oligomers containing these units [23, 50, 67, 68]. The nature of this interaction is unclear but has been suggested to be an electrostatic quadrupolar interaction between fragments having quadrupoles of opposite signs [69]. It is clear that the electron distributions in the differing mesogenic units for the MeOB6O.Om and MeOB6O.m series are rather similar and a specific favourable interaction between would not be expected, although we note that the dipole moments of these systems are rather different see Figure 11. For the CB6O.Om and CB6O.m series the specific favourable interaction between the unlike mesogenic groups presumably provides an additional force for the formation of both the $N_{TB}$ and N phases.
Figure 12. A comparison of the dependence of the twist-bend nematic-nematic transition temperatures, $T_{N_{TB}}$, on the length of the terminal chain $p$ for the MeOB6O.m (empty circles), MeOB6O.0m (filled circles), CB6O.m (empty squares) and CB6O.0m (filled squares) series. For the alkyl series $p = m$ and for the alkoxy series $p = m+1$.

Figure 13 compares the scaled entropies of transition associated with the nematic-isotropic transition, $\Delta S_{NI}/R$, on the length of the terminal chain for all four series. All the values are small and consistent with those expected for an odd-membered liquid crystal dimer [70]. The differences between the values are rather small when compared to experimental error although it appears that the cyanobiphenyl-based series tend to show slightly higher values and this reinforces the view that the nitrile group enhances the structural anisotropy of these materials [71, 72].
Figure 13. A comparison of the scaled entropy of transition associated with the nematic-isotropic transition, \( \Delta S_{NI}/R \), on the length of the terminal chain \( p \) for the MeOB\( 6O.m \) (empty circles), MeOB\( 6O.\text{Om} \) (filled circles), CB\( 6O.m \) (empty squares) and CB\( 6O.\text{Om} \) (filled squares) series. For the alkyl series \( p = m \) and for the alkoxy series \( p = m+1 \).

Of the four series of dimers discussed in this paper, all thirty-nine dimers exhibit nematic behaviour but just seven show smectic phases. This reflects the difficulties that bent odd-membered dimers experience in packing into smectic layered arrangements [56, 60, 61]. An intercalated Sm\( \text{CA} \) [23] or Sm\( \text{CTB} \) [49] phase is observed in the CB\( 6O.\text{Om} \) series for \( m=3-5 \) whereas at the same temperature, the corresponding CB\( 6O.m \) homologues show a nematic phase, and the MeOB\( 6O.m \) dimers either nematic or twist-bend nematic behaviour. The enhanced tendency for the CB\( 6O.\text{Om} \) to exhibit intercalated smectic behaviour may be attributed to an enhanced favourable specific interaction between the unlike mesogenic units [73]. These phases are only observed for intermediate chain lengths in the series because the terminal chain must be accommodated in the space defined by the length of the spacer. The absence of smectic behaviour for the CB\( 6O.m \) dimers reflects the relative difficulty in packing the alkyl chains which, as we saw earlier, protrude at some angle from the benzylideneaniline units into such an intercalated structure, whereas for the methoxybiphenyl-based dimers there is no specific interaction between the unlike mesogenic units to drive the formation of an
intercalated arrangement. The three longest members of the MeOB6O.m series exhibit a SmA phase whereas at the same temperature nematic or twist-bend nematic behaviour is seen for the corresponding homologues of the CB6O.Om and CB6O.m series. The monotropic nature of the smectic phases shown by these compounds precludes their study using X-ray diffraction but likely to have a monolayer arrangement [59]. The only direct comparison that is possible is between the transition temperatures of MeOB6O.10 and CB6O.10. The values of T_{NI} are essentially identical whereas MeOB6O.10 shows SmC-SmA and SmA-N transitions at 78 and 92 °C, respectively, and CB6O.10 a Sm_{N_TB} and N_{TB}N transitions at 67 and 73 °C, respectively. The stronger tendency of MeOB6O.10 to exhibit smectic behaviour suggests that the increased molecular inhomogeneity promotes microphase separation driving the formation of a smectic phase. For CB6O.10 for which the molecular inhomogeneity would appear very similar, microphase separation is counteracted by the specific favourable interaction between the unlike mesogenic units that promotes mixing. Furthermore, the decyl terminal chain is too long to be accommodated within an intercalated smectic structure and hence nematic behaviour is observed to lower temperatures.

4. Conclusions

The transitional properties of the MeOB6O.m and MeOB6O.Om series are broadly similar to those of the very few series already reported in the literature that exhibit the twist-bend nematic phase, and in which a terminal chain is varied in length. The data reported here allow us to begin to discuss what appear to be general patterns of behaviour. Thus, for both series the values of T_{NI} and T_{N_TB} show a modest alternation and in the same sense on increasing m. This counter-intuitive observation suggests that the spatial uniformity of molecular curvature is important in driving the formation of the N_{TB} phase. Furthermore, increasing the terminal chain length, increases the ratio T_{N_TB}/T_{NI} suggesting that the dilution of the interactions between the mesogenic units arising from increasing chain length has a relatively smaller effect on the predominantly shape driven N_{TB}-N transition than on the N-I transition. In addition, dimers with alkoxy terminal chains show higher values of both T_{NI} and T_{N_TB} than the corresponding alkyl substituted materials, and this may be attributed to the relative disposition of the chain with respect to the mesogenic moiety to which it is attached. These differences in transition temperatures become smaller as the chain length is increased. Again, this supports the view that the spatial uniformity of molecular curvature is important. Replacing a nitrile by a methoxy terminal group reduces both T_{NI} and T_{N_TB}, and again these reductions are smaller as the chain length is extended suggesting that they are associated with a change in molecular shape which is diluted as the molecule becomes larger. In these particular sets of materials the differences in transitional behaviour may be also be attributed, in part, to the specific favourable interaction between the cyanobiphenyl and benzylideneaniline moieties which are not present in the methoxybiphenyl-
based dimers. This is particularly true when considering the occurrence of smectic behaviour. The thirty-nine dimers discussed here are all predominantly nematogens and this reflects the difficulty bent dimers experience in packing into layered smectic arrangements. Intermediate members of the CB6O.OM series exhibit an intercalated smectic phase driven by the interaction between the unlike mesogenic groups. By comparison, the longest members of the MeOB6O.m series shown an enhanced tendency to exhibit smectic behaviour attributed to the molecular inhomogeneity arising from the long terminal chain.
