Potassium–carbonate co-substituted hydroxyapatite compositions: maximising the level of carbonate uptake for potential CO$_2$ utilisation options†

Duncan A. Nowicki,‡*† Janet M. S. Skakle $^{ab}$ and Iain R. Gibson $^{ba}$

CO$_2$ utilisation is a rapidly growing area of interest aimed at reducing the magnitude of anthropogenic greenhouse gas emissions. We report the synthesis of potassium–carbonate (K–CO$_3$) co-substituted hydroxyapatites with potassium and carbonate contents ranging from approximately 0.4–0.9 wt% and 3.4–13.0 wt% respectively via an aqueous precipitation reaction between calcium hydroxide, phosphoric acid and either potassium carbonate or potassium hydrogen–carbonate. The incorporated carbonate is situated on both hydroxyl and phosphate sites. A subsequent heat treatment in dry CO$_2$ at 600 °C allowed for a K–CO$_3$ co-substituted apatite containing approximately 16.9 wt% CO$_3$$^{2-}$ to be prepared, amongst the largest carbonate contents that have been reported for such a material to date. Although this work shows that K–CO$_3$ co-substituted apatites with high levels of carbonate incorporation can be prepared using simple, room temperature, aqueous precipitation reactions with starting reagents unlikely to pose significant environmental risks, testing of these materials in prospective applications (such as solid fertilisers) is required before they can be considered a viable CO$_2$ utilisation option. A preliminary assessment of the effect of potassium/carbonate substitution on the solubility of the as-prepared compositions showed that increasing carbonate substitution increased the solubility.

1. Introduction

The Intergovernmental Panel on Climate Change (IPCC) has projected that if current trends were to continue unabated, greenhouse gases such as CO$_2$ could become so concentrated in the atmosphere that by the year 2100 the global mean surface temperature of the Earth could be more than 4 °C warmer than it was during the pre-industrial era. Therefore, immediate action must be taken to reduce the magnitude of anthropogenic greenhouse gas emissions.

One route for achieving this is through the capture of CO$_2$ from large point sources such as fossil-fuel power stations and the subsequent utilisation of this gas in the preparation of functional materials; in addition to potentially permanently fixing the utilised CO$_2$, these products could also lead to a reduction in future CO$_2$ emissions by replacing current more ‘CO$_2$-intensive’ alternatives. For example, CO$_2$ could be used as a feedstock in the production of several important chemicals such as methanol, urea and salicylic acid or reacted with magnesium-rich brines to synthesise inorganic carbonates such as nesquehonite (MgCO$_3$·3H$_2$O) which could find application as a ‘green’ construction material. Carbon dioxide could even be reacted with promoter species in the presence of catalysts to form a range of environmentally benign polymers like poly(ethylene carbonate) and poly(propylene carbonate) which could replace conventional plastics.

In a similar manner, CO$_2$ gas could be utilised in the synthesis of a single-phase potassium–carbonate co-substituted hydroxyapatite. As phosphorus and potassium play important roles in plant growth, we speculate that such K–CO$_3$ co-substituted apatite materials could prove useful as solid fertilisers whilst allowing for captured CO$_2$ to be sequestered either in the solid materials themselves or in the soil to which the apatites are applied. However, careful characterisation of the uptake of CO$_2$ into these materials must be carried out first, to understand e.g. the role of reactant chemistry as a source of CO$_2$, levels of CO$_2$ incorporation that may be feasible, and the

role of thermal treatment in a CO₂ atmosphere to incorporate additional carbon dioxide. Whilst not yet explored in great detail as a potential CO₂ utilisation option, hydroxyapatite has already proven to have application in several fields including aqueous solution remediation, gas detection, agriculture as a fertiliser, ionic conduction and catalysis, and has been studied as a solid sorbent for carbon capture, with a previous study showing stoichiometric hydroxyapatite can adsorb approximately 0.06–0.07 mmol of CO₂ per gram of material when operating at 650–800 °C.¹⁵,²⁴

Hydroxyapatite, HA, (Ca₁₀(PO₄)₆(OH)₂) is a widely studied and adaptable calcium phosphate material. Its potential for CO₂ utilisation arises from the fact that the HA crystal structure can accommodate a significant quantity of CO₂ owing to its ability to substitute both hydroxyl (OH⁻) and phosphate (PO₄³⁻) groups for carbonate (CO₃²⁻) ions without compromising the crystal structure of the material. This is achieved through chemical substitution mechanisms, termed A-type and B-type substitution respectively. A-type substitution can be attained by heating stoichiometric HA at high temperature in an atmosphere of CO₂, where a single carbonate ion replaces two hydroxyl groups to allow overall charge balance to be maintained in accordance with the substitution mechanism shown below:

\[
\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2 + x\text{CO}_2 \rightarrow \text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2 - 2x(\text{CO}_3)x + x\text{H}_2\text{O}
\]

Accordingly, A-type carbonate substitution has a theoretical maximum substitution level, achieved once all hydroxyl groups have been replaced with carbonate (i.e., when \(x = 1\)). The substitution of phosphate groups for carbonate groups can be achieved by the synthesis of a phosphate-deficient apatite (Ca/P > 1.67) with concomitant carbonate substitution introduced through the water used in the aqueous synthesis and/or the calcining/sintering atmosphere. To maintain charge balance, this substitution also requires equimolar substitution of carbonate ions for hydroxyl ions. This substitution mechanism therefore has a limit on the maximum level of carbonate substitution as it relies on the limiting A-type substitution. A common synthesis mechanism for substituting carbonate ions for phosphate groups in the hydroxyapatite lattice is by co-substitution of carbonate with a monovalent cation, typically sodium ions but also ammonium or potassium ions. In these examples, some of the calcium ions are substituted for e.g., sodium ions allowing more carbonate to be incorporated into the structure, according to the charge-balance mechanism:

\[
(\text{PO}_4)^{3-} + \text{Ca}^{2+} \rightarrow (\text{CO}_3)^{2-} + \text{M}^{+}
\]

where \(\text{M}^+\) could be Na⁺, NH₄⁺ or K⁺. This gives the substitution mechanism \(\text{Ca}_{10-2x}\text{M}_x(\text{PO}_4)_{6-x}(\text{CO}_3)x(\text{OH})_2\). This mechanism focuses on balancing charge on the calcium and phosphate sites of HA, with any carbonate for hydroxyl substitution considered to occur independently. Our previous work showed that high levels of carbonate substitution, approximately 14 and 18 wt%, were achievable when sodium was the monovalent cation involved in the co-substitution, utilising NaCl and CO₂ gas or the more conventional sodium carbonate/sodium hydrogen carbonate reactants, respectively. In these compositions, however, the sodium counter ion does not provide any specific utilisation or benefit for an application of the material. Various methods, such as solid-state reaction, hydrothermal reaction, hydrolysis and ion-exchange, have been used to synthesise K–CO₃ co-substituted apatites with potassium and carbonate contents reported between approximately 0.4–6.9 wt% and 5.3–12.6 wt% respectively. Whyte et al. synthesised a number of K–CO₃ co-substituted hydroxyapatite materials, with substitution values of \(x = 0.1–1.0\), by aqueous precipitation reaction between calcium hydroxide (Ca(OH)₂), phosphoric acid (H₃PO₄) and potassium hydrogen–carbonate (KHCO₃). These compositions were designed in such a way that potassium and carbonate ions would substitute onto calcium and phosphate sites respectively to such an extent that the overall (Ca + K)/(P + C) molar ratio was 1.67. Although the carbonate content of the samples was not directly measured, FTIR analysis suggested that this increased with \(x\) as intended. The compositions were then heated for two hours at temperatures ranging from 600 to 1050 °C in either air or CO₂ to test their thermal stabilities. The authors observed that the temperature at which the materials decomposed to produce secondary phases of calcium oxide decreased with increasing values of \(x\) (i.e., with increasing K/(P+C) content) and also noted that decomposition occurred at higher temperatures when the samples were heated in an atmosphere of CO₂ compared to when they were heated in air.

The aim of the present work was to investigate the feasibility of using room temperature aqueous precipitation reactions between calcium hydroxide, phosphoric acid and either potassium carbonate or potassium hydrogen–carbonate to prepare several potassium–carbonate (K–CO₃) co-substituted apatite materials with high levels of carbonate incorporation. Potassium carbonate or potassium hydrogen–carbonate were chosen to provide the required K⁺ cations as both of these could theoretically be prepared on an industrial scale by reacting potassium hydroxide with captured CO₂. In some cases, this was followed by a heat treatment in a dry carbon dioxide atmosphere to determine what additional carbonate incorporation could be achieved. The prepared materials were characterised using a variety of techniques including powder X-ray diffraction and FTIR spectroscopy. A preliminary study was performed to assess the effect of the carbonate composition on the solubility of the compositions in an acidic buffer, to simulate the conditions of an acidic soil type.

2. Materials and methods

2.1. Synthesis of samples

Potassium–carbonate (K–CO₃) co-substituted apatites were synthesised at room temperature by aqueous precipitation reaction between calcium hydroxide (Ca(OH)₂, 98% assay, VWR, UK), phosphoric acid (H₃PO₄, 85% solution in water, Merck) and either potassium carbonate (K₂CO₃, ≥ 99% assay, Sigma-Aldrich, UK) or potassium hydrogen–carbonate (KHCO₃, 99.7% assay, Sigma-Aldrich, UK), following a method described
previously that was based on an established precipitation reaction. Briefly, two series of compositions were prepared with K₂CO₃ as the source of potassium ions in Series I and KHCO₃ used in Series II. Compositions based on the design formula Ca₁₀₋ₓKₓ(PO₄)₉₋ₓ(CO₃)ₓ(OH)₂ were prepared for x = 0–3 and the design compositions are provided in Tables S1 and S2 (ESI†). Precipitation reactions were maintained at an alkaline pH through the addition of 30 ml of aqueous NH₃ solution. The H₃PO₄ solution was added dropwise to the ‘calcium/potassium’ suspension of Ca(OH)₂ and K₂CO₃/KHCO₃ over a period of 2 hours, the mixture was aged overnight, filtered and washed with excess water, then the filter-cake was dried in an oven at 90 °C overnight. The dried filter cake was ground to a fine powder which was then subjected to a heat treatment in air at 300 °C for 1 hour using a muffle furnace (Carbolite Gero Ltd, UK), to remove synthesis residuals such as absorbed water; this did not affect the chemical composition of the materials markedly. Powders obtained after this heat treatment were designated ‘as-prepared’. Aliquots (c. 0.5 g) of a selected composition were heated in a tube furnace (Carbolite Gero Ltd, UK) under a dry CO₂ gas flow rate of approximately 0.5 dm³ per minute. The temperature in the furnace was ramped from ambient up to the desired heating temperature of 300–700 °C at a rate of 5 °C min⁻¹, held there for one hour and then cooled back to room temperature at the same rate.

2.2. X-ray diffraction analysis

X-ray diffraction (XRD) patterns were collected with a X’Pert Pro diffractometer (PANalytical Ltd, UK), operating at 45 kV and 40 mA with Cu Kα radiation (λ = 1.5418 Å). Data were collected from 15 to 65° 2θ with a step size of 0.013° and a count time per step of 96 s. Crystalline phases present were identified by comparing obtained patterns with PDF files from the ICDD database. The average crystallite sizes were calculated using the Scherrer equation, using the (002) reflection at approximately 25.8° 2θ, and with k = 0.9. A highly crystalline quartz standard was used to compute the instrumental line broadening. Lattice parameters were determined by simple Rietveld refinement of collected XRD data using the PANalytical software package ‘HighScore Plus’. Refinements were carried out using the hexagonal space group P6₃/m using hydroxyapatite data reported by Sudarsanan and Young as the initial structural model. Only the background function, scale factor, unit cell parameters and peak shape functions were refined.

2.3. Chemical composition analysis

The Ca/P molar ratio, potassium content and thus the (Ca + K)/P molar ratio of each sample was determined by energy-dispersive X-ray spectroscopy (EDX) using a Gemini SEM 300 field emission SEM (Zeiss, Germany) equipped with an X-ray detector (Oxford Instruments, UK) operating at an accelerating voltage of 15 kV. A powder compact was coated with carbon prior to analysis. For each sample, three measurements were taken and the results reported as an average alongside the standard deviation. The carbonate contents of samples were determined using a LECO CS744 carbon/sulphur analyser (LECO Instruments UK Ltd, UK). For each sample, duplicate measurements were made and the mean value reported alongside the standard deviation. It was assumed that all of the carbon detected by the equipment existed as CO₂, which was reasonable as the equipment flopped the combustion chamber with oxygen and also passed the combustion products through an oxidation catalyst.

2.4. FTIR analysis

FTIR spectra were obtained using a Diamond/ZnSe ATR attached to a Spectrum Two™ spectrometer (PerkinElmer, UK). Absorbance spectra were collected at a 2 cm⁻¹ resolution between 4000 and 400 cm⁻¹, averaging 7 scans per sample. Peak deconvolution of the carbonate ν₂ (850–890 cm⁻¹) and ν₃ (1300–1600 cm⁻¹) regions and the phosphate ν₄ (485–700 cm⁻¹) region of the spectra was performed by fitting Gaussian distributions, using the Solver extension in Excel, based on peak assignment described elsewhere; a linear background was subtracted prior to deconvolution.

2.5. Dissolution evaluation

The relative solubilities of the different compositions were assessed by incubating as-prepared powder samples (sieved to 53–315 µm size) in an acidic (pH 5.5) buffer solution for 30 minutes and measuring the Ca ion concentration, based on a method described by Mano et al.,. For each composition studied, 30 mg of sample was incubated in 20 ml of 0.08 M sodium acetate–acetic acid buffer solution, prepared as described elsewhere, for 30 minutes at 20 °C, under 150 rpm mixing. A 100 µl aliquot was collected for the measurement of Ca ion concentration in the buffer solution. For each composition 3 replicates were prepared.

The calcium ion concentration was determined using a colorimetric assay based on the ortho-cresolphthalein complexone (o-CPC) method described by Connerty et al.. Briefly, stock solutions of 1.66 mM o-CPC (64000-1G, Sigma Aldrich, UK), 0.344 M 8-hydroxyquinoline (8-HQ) (H6878-25G, Sigma Aldrich, UK) and 14.8 M ethanolamine (1008451000, Sigma Aldrich, UK) were prepared. A working solution was prepared by combining these three stock solutions to achieve final concentrations of o-CPC and 8-HQ of 0.083 mM and 6.89 mM, respectively, and the concentration of ethanolamine was 0.74 M. A series of Ca²⁺ standards were prepared by diluting a 1000 ppm Ca²⁺ standard (21049-100ML, Sigma Aldrich, UK) in water. In a 96 well plate 300 µl of working solution per well was added to 10 µl of each standard/test sample to be measured, the mixture was allowed to react for 5 minutes, then the absorbance at 575 nm was read on a plate reader (BioTek Synergy HT). For each Ca²⁺ standard duplicate wells were prepared, and for each test sample triplicate wells were prepared.

2.6. Statistical analysis

Comparison of dissolution data from multiple groups (x = 0–2.0) was performed with GraphPad Prism (v5.04, GraphPad Software Inc., USA) using one-way analysis of variance (ANOVA) with a post hoc Tukey’s test. For assessment of differences in dissolution
data for $x = 1.5$ from samples synthesised with two different sources of potassium, a $t$-test was used. Results are reported as mean ± SD. Values of $p < 0.05$ are considered to be statistically significant.

## 3. Results and discussion

### 3.1. As-prepared apatites

#### 3.1.1. X-ray diffraction (XRD) analysis

XRD patterns of the as-prepared powders of each series are shown in Fig. 1. In Series I (when K$_2$CO$_3$ was used), the compositions were phase-pure apatites by XRD for design substitution values up to and including $x = 2.5$; all of the reflections in the collected patterns were comparable to the ICDD standard$^{40}$ for hydroxyapatite. By comparison, the compositions of Series II (when KHCO$_3$ was used) were single-phase apatites only up to $x = 1.5$. Although this study did not explore the reasons for these differing limits, it would seem reasonable to conclude that this disparity was related to the nature of the potassium reagents themselves. For example, perhaps the lower $x$-value achieved using KHCO$_3$ was a result of HCO$_3$ ions having substituted into the lattice or (as KHCO$_3$ is significantly less basic than K$_2$CO$_3$)$^{41}$ as a result of a lower reaction mixture pH (the pH of the aged reaction mixtures of Series II tended to be up to a full integer lower than their counterparts of Series I). Also, the HA reflections in all of the collected patterns were quite broad which indicated that each hydroxyapatite phase was composed of very small crystallites as would be expected when using an aqueous precipitation synthesis route.$^{42,43}$ Above these limits of $x$, an impurity phase of calcite (CaCO$_3$) was observed to form alongside the apatite phase; diffraction peaks attributable to these secondary phases are explicitly marked in Fig. 1. Crystalite sizes were calculated using the Scherrer equation, using the (002) reflection of HA at approximately 25.8° 2θ, and were of the order of 18–29 nm, with some correlation between the design composition and crystallite size, Table S3 (ESI†).

The unit cell parameters of the as-prepared apatites are shown in full in Table S4 (ESI†) and are plotted as a function of the design composition value of $x$ and of the measured carbonate content (described later in Section 3.1.2) of the materials in Fig. 2. In each series, there was a linear contraction in the $a$ lattice parameter and the unit cell volume as the design $x$-value increased; this linear contraction was also observed when plotted against the measured carbonate contents. There was a linear decrease in the $a$ lattice parameter with increasing measured potassium content for the design compositions between $x = 0–1.5$, but there was then a loss in any correlation for higher values of Series I (plotted data not shown, but data are provided in Tables S4–S6, ESI†). It is known that B-type carbonate substitution causes the $c$-axis to expand and the $a$-axis to contract, whilst A-type carbonate substitution has the opposite effects on the unit cell parameters of HA.$^8$ Therefore, although there was no clear trend in the $c$ unit cell parameter in either series with $x/K'/CO_3^{2-}$ content, the variations in the $a$ lattice parameter and the unit cell volume suggested that the substitution of carbonate ions on phosphate sites had more of an impact on the hydroxyapatite crystal structure, and thus the dimensions of the unit cell of the as-prepared material, than did the substitution of carbonate ions on hydroxyl sites.

![Fig. 1](image-url) Normalised ($I_{max} = 100$) XRD patterns between 15–65° 2θ of the as-prepared samples of Series I (A) and Series II (B), where $x = 0–3.0$ in the design formula Ca$_{10-x}$K$_x$(PO$_4$)$_6$·(CO$_3$)$_x$(OH)$_2$. Intense reflections corresponding to impurity phases of calcite are marked using .
3.1.2. **Chemical analysis.** The potassium content as well as the Ca/P and (Ca + K)/P molar ratios of the as-prepared apatites were measured using EDX and their carbonate contents measured using combustion analysis. The results of this analysis are presented in full in Tables S5 and S6 (ESI†) and demonstrate that the chemical composition of these as-prepared materials did not match the design formula. Although potassium ions were indeed present in each of the as-prepared apatites, all of these compositions contained significantly less of these cations than the design amount irrespective of the potassium reagent used in the precipitation reaction, Fig. 3A. In Series I, the measured potassium content of the materials appeared to level out once a certain value of x had been achieved, suggesting that a maximum existed at approximately 0.9 wt% potassium. These lower than expected potassium contents (and the failure to detect any impurity phases using XRD) suggested that, instead of having substituted into the apatite lattice, most of the potassium cations that were added to the reaction mixture had remained in solution and then been lost during the filtration step. Synthesis of sodium/carbonate substituted hydroxyapatite compositions also observed lower than expected levels of sodium substitution, even though increasing amounts of sodium carbonate reactant added resulted in increasing levels of carbonate substitution.\(^{25}\) \(\text{NH}_4^+\) ions are known to be capable of substituting for the calcium ions in hydroxyapatite\(^{44}\) and it could therefore be hypothesised that perhaps some competition existed between \(\text{K}^+\) ions and \(\text{NH}_4^+\) ions for the open calcium sites. C–H–N analysis was performed on several of the as-prepared apatites but this failed to detect the presence of nitrogen in any of the samples (data not shown). Even so, it is possible that nitrogen existed in very small amounts that could not be detected by the equipment or that this element had been removed during the heat treatment in air at 300 °C and so the synthesis of the \(x = 0.5\) and \(x = 2.5\)
solution did not lead to the preparation of apatites with larger potassium contents. The exclusion of ammonia NH₄OH solution to the calcium/potassium suspension. While EDX analysis provides a quantitative measure of the trend in increasing Ca/P molar ratio and K content with increasing substitution, additional analytical quantification by spectroscopy methods such as ICP-OES, would provide more precise quantification of the chemical compositions.

In both series, the measured Ca/P molar ratio increased linearly with x. This signalled that the relative content of phosphate ions in the apatites decreased as the design substitution value rose in order to accommodate the substitution of carbonate ions onto B-sites as designed. While the measured Ca/P molar ratios of the apatites prepared using KHCO₃ were comparable to the design values, this ratio was invariably smaller than designed in the apatites of Series I. The measured (Ca + K)/P molar ratio of every apatite was lower than designed, a result primarily of the much smaller than expected potassium contents. The carbonate content also increased linearly with increasing x in each series. Although the greatest CO₃²⁻ content (13.0 wt%) was achieved using K₂CO₃ for x = 2.5, the carbonate contents of Series I were smaller than equivalent design compositions (x values) prepared using KHCO₃ and also tended to be smaller than was expected according to the design formula. Nevertheless, these results support the concept that a two-step process could be developed where K₂CO₃ or KHCO₃ is first produced using captured CO₂ and then used in the precipitation of highly carbonated K–CO₃ co-substituted apatites.

In an effort to increase the maximum degree of carbonation, the synthesis of each series was repeated with CO₂ gas bubbled into the H₃PO₄ solution during the precipitation reaction to create an excess of carbonate ions in the reaction mixture. This gas was bubbled into the H₃PO₄ solution for 30 minutes prior to this solution being added dropwise to the basic suspension and was maintained until the addition of the H₃PO₄ solution was complete. The dissolution of CO₂ gas, and the subsequent evolution of carbonic acid (H₂CO₃), did not affect the temperature of the H₃PO₄ solution and by extension the reaction mixture to any significant extent. Whilst the bubbling of this gas into the H₃PO₄ solution led to a significant increase in the carbonate content of the apatites of Series I at low values of x, its influence diminished markedly as the design substitution value increased (Table 1). For example, the x = 2.5 apatite prepared using K₂CO₃ and with CO₂ gas bubbled into the H₃PO₄ solution contained 14.1 wt% of carbonate, only marginally larger than the 13.0 wt% seen in the x = 2.5 apatite of Series I. Instead, the carbonate ions that were introduced into the reaction mixture from the potassium reagent itself (in addition to those present from the dissolution of atmospheric CO₂) were sufficient to reach the high levels of carbonation that were achieved. The differences in the measured carbonate content in the KHCO₃ series, with or without gas added during the reaction, were much smaller, for any x value, than the K₂CO₃ series; per mole of potassium, the KHCO₃ reactant provides more carbonate to the reaction, so this may explain this observation.

### 3.1.3. Fourier-transform infrared spectroscopy (FTIR)

FTIR spectra of the as-prepared K–CO₃ co-substituted apatites are presented in Fig. 4. These spectra were comparable to those seen in other studies of apatites prepared by aqueous precipitation reaction. The four IR-active phosphate vibrations that are characteristic of hydroxyapatite were observed in each spectrum. These appeared to broaden slightly in each series as the design substitution value increased, which may have been due to decreasing crystallite size along the c-axis. In addition, a broad band (centred at approximately 1640 cm⁻¹)
attributed to the presence of absorbed water.\(^\text{(48)}\) was visible in each spectrum although this was very weak. The presence of this vibration indicated that neither the oven drying nor the heat treatment in air at 300 °C had fully dried the materials. Vibrations corresponding to the librational and stretching modes of hydroxyl ions were observed in the compositions of both series (at approximately 631 and 3570 cm\(^{-1}\) respectively) at low values of \(x\). Carbonate \(v_1\) and \(v_2\) bands were also visible in each of these spectra, Fig. 4A, C, D and F, with contributions corresponding to the substitution of carbonate ions on hydroxyl and phosphate sites, consistent with previous studies.\(^{8,49–52}\)

An example of the peak deconvolution of the OH libration and PO\(_4\) \(v_1\) region is shown in Fig. 5A and B for the design composition \(x = 1.5\) of Series I and Series II, respectively, and the peak positions (numbered from 1a–5a from the highest to the lowest wavenumber) and areas of the phosphate \(v_1\) region, including the OH libration, are listed in full in Table S8 (ESI\(^*\)). Assignment of vibrations in carbonate-containing apatites can be challenging as many parameters that are specific to a given study, such as chemical composition, preparation method, monovalent ion content, thermal treatment temperature and atmosphere can influence the peak positions and intensity of carbonate and phosphate vibrations, so definitive assignment based on literature data must be made with caution. In addition to the expected three PO\(_4\) vibrations (peaks 2a, 3a and 4a) at approximately 604–601, 582–576 and 565–561 cm\(^{-1}\), a peak at approximately 545–540 cm\(^{-1}\) (peak 5a) was assigned to HPO\(_4\) groups in the apatite structure.\(^{53}\) The peak area of this vibration appeared to decrease slightly with increasing \(x\) value in both Series I and II. Peak deconvolution established a peak with decreasing intensity at 631–626 cm\(^{-1}\) (peak 1a) as the value of \(x\) increased, which is assigned to hydroxyl libration. The three peaks of the triply degenerate bending mode of the PO\(_4\) \(v_1\) region did not show any strong trend in peak position or peak area with increasing substitution or between the two series, although there appeared to be a slight shift to higher wavenumber of the \(v_{4b}\) vibration (peak 3a) from 576 cm\(^{-1}\) for \(x = 0\) up to 582 cm\(^{-1}\) for \(x = 2.5\). The carbonate \(v_2\) region produced a very broad band with poor definition of individual vibrations and peak deconvolution required 7–8 peaks to achieve a reasonable fit, although for the highest level of substitution, \(x = 2.5\), Series I, a reasonable fit to 3 peaks was possible. The most intense peaks from the fit were at approximately 877–875, 870–868 and 863–848 cm\(^{-1}\), which are consistent with assignments to A-type (for hydroxyl), B1-type (for phosphate) and B2-type (for phosphate) carbonate substitution, respectively,\(^{51}\) but with a small downshift. A vibration in the region 863–861 cm\(^{-1}\) has been assigned to labile carbonate, HPO\(_4\) groups and B2-type carbonate, depending on the composition, so care should be taken in the assignment of this peak in this broad, poorly resolved \(v_2\) region. Peak deconvolution of the carbonate \(v_1\) regions produced a fit comprising 6 peaks, with examples for the design composition of \(x = 1.5\) of Series I and Series II shown in Fig. 5C and D. The peak positions and areas (arbitrarily numbered from 1b–6b from the highest to the lowest wavenumber) of the carbonate \(v_1\) region from the spectra of all single-phase as-prepared compositions in Series I and II are listed in full in Table S8 (ESI\(^*\)). Three peaks (2b, 3b and 5b) are dominant in the substituted samples, in terms of their peak areas, at 1492–1486 cm\(^{-1}\), 1456–1447 cm\(^{-1}\) and 1412–1401 cm\(^{-1}\); the \(x = 0\) sample produced low intensity vibrations in this region and the peak positions were all closer in peak areas, except the peak at 1417 cm\(^{-1}\) which dominated, and peak positions were typically 10–20 cm\(^{-1}\) higher than the positions of corresponding peaks in the substituted samples. Peak 2b (1492–1486 cm\(^{-1}\)) can be assigned to A-type substitution and peak 5b (1412–1401 cm\(^{-1}\)) can be assigned to B-type substitution.\(^{8,49–52,54–56}\) Assignment of peak 3b (1456–1447 cm\(^{-1}\)) to literature data does not have such a clear consensus, with studies assigning this to both A-type substitution\(^{49,51,56}\) and B-type substitution.\(^{50,54,55}\) In our own recent study, A-type carbonate substituted hydroxyapatite produced peaks at approximately 1532 and 1465 cm\(^{-1}\) with similar peak areas.\(^{57}\) The peak area of the peak in the 1557–1523 cm\(^{-1}\) region in the current study contributes a much smaller amount to the total peak area of the \(v_1\) region than the peak at 1456–1447 cm\(^{-1}\), Table S8 (ESI\(^*\)), suggesting that the latter peak reflects some contribution of A-type carbonate in this region, but relates more to B-type carbonate. Weaker bands (peaks 1b, 4b and 6b) at 1537–1523 cm\(^{-1}\), 1424–1419 cm\(^{-1}\) and 1393–1355 cm\(^{-1}\), show some small changes in peak position and area with increasing substitution and between Series I and II, but the most notable was the shift to lower wavenumbers of peak 1b, from approximately 1565 cm\(^{-1}\) for \(x = 0\) to 1523 cm\(^{-1}\) for \(x = 2.5\). Studies on Na-containing apatites have described distinct A-type vibrations, with bands at 1540 and 1449 cm\(^{-1}\) assigned to type-A1, and type A2 to bands at 1569 and 1507 cm\(^{-1}\).\(^{58}\) Peak 1b could be assigned to type A1, with some intensity also within the peak 3b. No clear vibration was identified at approximately 1473 cm\(^{-1}\) which is commonly assigned to B-type substitution, nor a peak at approximately 1565 cm\(^{-1}\) which is commonly assigned to A-type substitution. Yoder et al. produced a potassium–carbonate substituted hydroxyapatite using KHCO\(_3\) which had measured potassium.
(0.51 wt%) and carbonate ion (5.99 wt%) contents that were comparable to \( \chi = 0.5 \) of Series II in this study (Table S6, ESI†) and, without peak deconvolution, identified carbonate vibrations at 1490 and 1540 cm\(^{-1} \) that were assigned to A-type and 1417 and 1451 cm\(^{-1} \) that were assigned to B-type carbonate.\(^{54} \) A band at 1387 cm\(^{-1} \) has been assigned to carbonate in a water compartment, described as within water trapped in pores within grains, or water that is surface adsorbed\(^{49} \) and, as a weak vibration from the presence of water was visible, this is feasible. No vibrations characteristic of calcite or aragonite were observed at \( \approx 713 \) or 700 cm\(^{-1} \) in any of these spectra, confirming the absence of a calcium carbonate impurity in these samples;\(^{59} \) a peak at 714 cm\(^{-1} \) was observed in the spectrum of the \( \chi = 3.0 \) sample of Series I (data not shown), which showed an impurity of calcite by XRD (Fig. 1). Overall it appears that increasing levels of carbonate and potassium substitution have little impact on the vibrations present and their relative contributions to total carbonate in the as-prepared samples of Series I and II.

3.1.4. Dissolution evaluation. To identify if increasing the amount of potassium/carbonate substitution would affect the solubility of hydroxyapatite, powder samples of the Series I as-prepared compositions for \( \chi = 0.5 \) to 2.0, Series II composition with \( \chi = 1.5 \), and an unsubstituted composition (\( \chi = 0 \)) were incubated in an acidic (pH 5.5) buffer for 30 minutes, then the Ca\(^{2+} \) ion concentration in the buffer solution measured using a colorimetric assay, Fig. 6. Increasing the design composition in Series I, resulting in an increase in carbonate content, and to a lesser extent an increase in potassium content from \( \chi = 0.5 \) to 1.5 (Tables S5 and S6, ESI†), resulted in an increase in solubility.

Fig. 4 Normalised (\( A_{\text{max}} = 100 \)) FTIR absorbance spectra of the single-phase as-prepared apatites of Series I (A–C) and II (D–F), where \( \chi = 0–2.5 \) in the design formula Ca\(_{10-\chi}\)K\(_{\chi}\)(PO\(_4\))\(_6\)\(\chi\)(CO\(_3\))\(_\chi\)(OH)\(_2\).
under acidic conditions, with a significant increase in the calcium ion concentration of the buffer solution for design compositions with $x = 1.5$ and 2.0 ($p < 0.05$), compared to the unsubstituted $x = 0$ HA, Fig. 6A. Comparing the two sources of potassium carbonate, the $x = 1.5$ composition prepared with KHCO$_3$ (Series II) resulted in a higher calcium ion concentration of the buffer solution than the $x = 1.5$ composition prepared with K$_2$CO$_3$ (Series I), Fig. 6B. The former had a higher measured carbonate content (9.58 wt%) than the latter (7.9 wt%), while both had comparable potassium contents (Tables S5 and S6, ESI$^+$), which supports the view that the carbonate content of the materials correlates with the solubility. Plotting the calcium ion concentration in the buffer solution against the measured carbonate contents of the co-substituted samples from Fig. 3 produced a linear fit with $R^2 = 0.986$, (data not shown). Xiong et al. studied the effect of surface charge of HA nanoparticles on the P release of hydroxyapatite nanoparticles as potential alternatives to triple super phosphate (TSP) fertilisers (monocalcium phosphate) in an acidic soil ($pH$ 4.7) and observed that sustained release of phosphate was dependent on the HA nanoparticles; an electronegative surface charge resulted in the HA nanoparticles having a slower and more sustained release of phosphorus than the TSP fertiliser.$^{22}$ Our data, while preliminary, suggests that modifying the composition of hydroxyapatite nanoparticles by potassium/carbonate co-substitution is another method to control the solubility, and

|Fig. 5| Deconvolution of the (A and B) O$_{35}$ and PO$_4$ $v_3$ and (C and D) CO$_3$ $v_3$ regions of the FTIR spectra of the as-prepared $x = 1.5$ compositions for (A and C) Series I (K$_2$CO$_3$) and (B and D) Series II (KHCO$_3$) potassium-carbonate co-substituted samples showing the various vibrations that contribute to the observed spectra; $y$-axis is an arbitrary scale. Dashed lines correspond to the individual fitted peaks and the solid line is the corresponding model spectra, with the raw data presented as isolated data points. |
therefore the phosphorus release, with the additional potential of a concomitant release of potassium ions (albeit in much smaller quantities than would have been predicted from the design formula).

3.2. Heated apatite(s)

3.2.1. X-ray diffraction (XRD) analysis. The $x = 2.5$ apatite of Series I was subjected to several heat treatments in dry CO$_2$ to test if the degree of carbonate substitution in the material could be increased. This composition was chosen as it exhibited the largest carbonate content of all of the as-prepared apatites. XRD patterns of samples heated at 300–700 °C are presented in Fig. 7. Whilst the material remained as a phase-pure apatite after it was heated at 300–600 °C, a secondary phase of calcite was produced after heat treatment at 700 °C. This impurity phase would likely have initially formed as CaO due to the calcium-rich (i.e. Ca/P molar ratio $>1.67$) nature of the composition, but due to the CO$_2$ atmosphere of the heat treatment underwent carbonation to form calcite. The formation of this secondary phase demonstrated that this K–CO$_3$ co-substituted apatite was significantly less thermally stable than stoichiometric HA, which has been shown to be stable in dry or moist air up to approximately 1200 °C. This disparity was to be expected and can be explained by examining the differing mechanisms which govern the thermal decomposition of stoichiometric HA and CHAs. Whereas stoichiometric HA is known to decompose as a result of a loss of channel hydroxyl groups above a certain temperature via an oxyhydroxyapatite intermediate, CHAs are understood to decompose upon heating due to the loss of substituted carbonate groups as CO$_2$. Whilst the loss of hydroxyl groups has been reported to begin at approximately 1000 °C in air, the loss of carbonate groups from the HA lattice typically begins at much lower temperatures.

The lattice parameters of the K–CO$_3$ co-substituted apatites after being heated in dry CO$_2$ at 300–600 °C are shown in full in Table S9 (ESI) and plotted as a function of the heat treatment temperature in Fig. 8. Both the $a$ and $c$ unit cell parameters (as well as the unit cell volume) of the heated samples tended to be larger than the as-prepared material, with the magnitude of these expansions proportional to the temperature at which the heat treatments were performed. These trends can be explained by considering two scenarios. The first is that CO$_3^{2-}$ ions had
substituted during the heat-treatment exclusively for the relatively smaller hydroxyl groups and oriented mostly parallel to the ab plane, producing the observed expansions in the a parameter and the unit cell volume in accordance with Vegard’s law. Although expansions in the c unit cell parameter are not usually associated with this type of carbonate substitution, the expansions were relatively small and so could be accounted for by a non-parallel component in the orientation of the substituted carbonate groups. A-type carbonate substitution is usually associated with higher temperatures treatments in a CO₂ atmosphere for long durations of time, but appreciable A-type substitution can occur at lower temperatures and for shorter time periods. Alternatively, carbonate ions may have simultaneously substituted onto both hydroxyl and phosphate sites. Here, the relative expansions of a and c could be used as evidence that the heat treatment had brought about significantly more CO₃²⁻ substitution on the A-sites than it did the B-sites. Unfortunately, the quality of the diffraction patterns of these nanoscale samples did not allow for a full structure refinement (such as atomic coordinates and site occupancy) to be performed, which is a similar problem to diffraction data from bioapatites.

### 3.2.2. Quantitative carbonate analysis

The results of combustion analysis performed on the x = 2.5, Series I samples that had remained as phase-pure apatites after the heat treatments in dry CO₂ are shown in Table 2. Each of the heated samples contained more carbonate than in the as-prepared sample. There was a consistent increase in the carbonate content of the apatite as the temperature increased from 300–600 °C, which suggested that over this temperature range, the carbonate ions previously incorporated into the apatite had been preserved, likely as a result of the CO₂ atmosphere in which the heat treatments were performed. After it had been heated in dry CO₂ at 600 °C, the apatite material contained approximately 16.9 wt% of carbonate. We believe that this may be the largest carbonate content that has been observed for a single phase K–CO₃ co-substituted apatite to date, with other such materials having been reported to contain between 4.95–12.6 wt% of carbonate.

Self-evidently, one of the key performance indicators as to the viability of a given CO₂ utilisation option is the quantity of carbon dioxide that can be stored. Table 3 demonstrates that the equivalent quantity of carbon dioxide incorporated during the synthesis of this apatite was of the same order of magnitude, but lower than, a number of other widely proposed utilisation options. However, it should be kept in mind that all sectors must be decarbonised if net-zero is to be achieved and it is to be expected that some options will perform better than others with regards to this indicator.

#### 3.2.3. FTIR analysis of heated samples

FTIR spectra of the potassium–carbonate co-substituted apatite material (x = 2.5, Series I) after it had been subjected to the heat treatments in dry CO₂ are displayed in Fig. 9. The heat treatments caused the broad band at approximately 1640 cm⁻¹, attributable to the presence of absorbed water, to disappear. Additionally, heating the apatite improved the resolution of the contributions corresponding to A and B-type carbonate substitution in the v₁ and v₂ carbonate regions, Fig. 9B and C. As for the as-prepared samples, deconvolution of the OH₃ and PO₄ v₃ region revealed the expected 3 peaks (peaks 2A–4A) related to the PO₄ vibrations in apatites, with no significant change in position or relative peak area with increasing heat treatment temperature.

as the temperature increased, which would be consistent with loss of hydroxyl groups on heating. Peak deconvolution of the carbonate \( v_3 \) region of the heated samples showed some clear differences from the as-prepared samples, Table 4 and graphically for the sample heated at 500 \( ^\circ\mathrm{C} \) in Fig. 10A; this also used a six-peak fit (peaks 1B–6B). The main peaks assigned to A-type carbonate substitution in the as-prepared samples, at 1523 and 1492 cm\(^{-1}\) in the \( x = 2.5 \) sample (peaks 1B and 2B), remain in all heated samples with comparable contributions (by % peak area) to the total \( v_3 \) region. The peak at 1401–1410 cm\(^{-1}\) (peak 5B) that was assigned to B-type substitution in the as-prepared samples was again a dominant peak, but appeared to shift considerably to 1418 cm\(^{-1}\) after heating at 600 \( ^\circ\mathrm{C} \). A peak at 1415–1417 cm\(^{-1}\) (peak 4B) has been assigned to B-type substitution in many studies, so the similarity in peak area of the peak in the 1401–1418 cm\(^{-1}\) region supports this is a shift as a result of heating to 600 \( ^\circ\mathrm{C} \). The peak at approximately 1446–1455 cm\(^{-1}\) (peak 3B) that appears in as-prepared samples decreased in contribution with heating. For samples heated at 500–600 \( ^\circ\mathrm{C} \) a peak at 1472–1479 cm\(^{-1}\) appeared which is commonly reported in carbonate-substituted apatites and is assigned to B-type carbonate. This peak increased in relative peak area at the expense of the decreasing peak at 1446–1465 cm\(^{-1}\). While the resolution of the \( v_3 \) region improves with heating the total band is very broad and in this region, where different studies have assigned vibrations in the region 1445–1455 cm\(^{-1}\) to both A and B-type substitution, care should be taken to assign the different deconvoluted peaks.

What is clear is that heating the as-prepared \( x = 2.5 \) sample has resulted in some structural change with changes in peak position and relative intensity in the 1400–1480 cm\(^{-1}\) region.

From analysis of these heated samples the vibration at 1368–1379 cm\(^{-1}\) (peak 6B) is not likely due to carbonate in a water environment, as proposed by Kafkač et al.,\(^{49}\) the relative peak area % increased slightly after heating in CO\(_2\) and the water bending vibration at approximately 1640 cm\(^{-1}\) that was visible in

---

**Fig. 9** Normalised \( A_{\text{max}} = 100 \) FTIR spectra of the \( x = 2.5 \) apatite of Series I as-prepared (AP) and after being subjected to heat treatments in dry CO\(_2\) at 300–600 \( ^\circ\mathrm{C} \).
the as-prepared samples disappeared. A band at 1384 and 1386 cm\(^{-1}\) was assigned to A-type carbonate in sodium–carbonate substituted apatites.\(^{56}\) Heating the as-prepared samples also improved the resolution of the carbonate v\(_2\) region and the peak deconvolution was successful with 4 peaks, or 3 peaks for the AP and the 300 °C heat treatment, Table 4 and the example for 500 °C in Fig. 10B. Peak 1C at 880–876 cm\(^{-1}\) can be assigned to A-type carbonate substitution and shows a small shift to higher frequency,\(^{51}\) and their summed relative peak area shows a small increase with increasing heat treatment temperature. A peak (peak 2C) at 872–868 cm\(^{-1}\) is observed at all conditions and between 400 and 600 °C a second peak (peak 3C) can be fitted at 856–855 cm\(^{-1}\); these can be assigned to B1- and B2-type carbonate, with a small downshift to lower frequency,\(^{51}\) and their summed relative peak area shows a small increase with increasing heat treatment temperature. A peak (peak 4C) at 857–858 cm\(^{-1}\) is present before and after all of the heat treatments and represents about 8–11% of the total peak area. The presence of this peak somewhat mirrors the peak at 1368–1379 cm\(^{-1}\) in the carbonate v\(_2\) region, and this could be attributed to a second A2-type carbonate band. It is known that carbonate environments in sodium-bearing carbonate substituted hydroxyapatites are influenced by the presence of the monovalent sodium ions, so the presence of potassium in the materials described here may also have a local influence on the carbonate environments.

Estimation of the carbonate content from the FTIR data of the as-prepared compositions and the heat-treated x = 2.5 samples was performed and compared to the carbonate content (wt%) measured from combustion analysis data, Tables 1 and 2. A number of approaches have been reported in the literature for quantifying the carbonate content in apatites from the FTIR data, including determining carbonate to phosphate ratios from peak intensities or from peak areas, using isolated peaks or specific regions, and also using v\(_3\) or v\(_4\) phosphate regions and v\(_3\)/v\(_4\) or v\(_4\) phosphate regions of the spectra.\(^{69}\) As the deconvolution of the carbonate v\(_3\) region of the as-prepared samples was limited, and the poorly defined and overlapping v\(_3\)/v\(_4\) phosphate regions results in assumptions being made, the carbonate to phosphate ratios determined were based on (i) the total v\(_3\) carbonate peak area divided by the total v\(_4\) phosphate peak area excluding the OH\(_x\) peak, and (ii) the peak intensity ratio (PIR) of the carbonate band at ~1415 cm\(^{-1}\) (in practise 1401–1418 cm\(^{-1}\)) divided by the peak intensity of the v\(_4\) phosphate band at ~604 cm\(^{-1}\).\(^{47}\) The measured carbonate contents (wt%) by combustion analysis of all the as-prepared and heated samples were then plotted against the peak area ratios of the CO\(_3\) v\(_3\) and PO\(_4\) v\(_4\) regions, Fig. 11A, and the peak intensity ratios of the CO\(_3\) v\(_3\) vibration at approximately 1410 cm\(^{-1}\) and the PO\(_4\) v\(_4\) vibration at approximately 603 cm\(^{-1}\), Fig. 11B, with linear fits applied to the data. Both methods provide good linear fits to the data (R\(^2\) values of 0.978 and 0.939, respectively), even though this combines data using two different potassium carbonate reactants and also as-prepared and heat treated samples. This confirms that the total carbonate content of samples increases with both increasing substitution design level, and with increased temperature of heat treatment. In terms of the distribution of carbonate ions over hydroxyl and phosphate sites, so A-type and B-type, the ratio of the peak areas assigned in the v\(_2\) region is commonly used to describe a B/A ratio, with this being extended when including duplicate bands (B1 and B2, and A1 and A2) have been assigned.\(^{51}\) If the peak at 857 cm\(^{-1}\) is not included, the (B1 + B2)/A1 peak area ratio, based on the assignment described above, shows an increase with increasing heat treatment temperature, from 1.2, 2.1, 2.1, 2.9 and 2.9 for AP, 300, 400, 500 and 600 °C (including the 857 cm\(^{-1}\) peak, so the (B1 + B2)/(A1 + A2) ratio, provides values of 1.0, 1.5, 1.6, 1.9 and 2.2. The increase in carbonate content of the x = 2.5 composition with increasing temperature is therefore associated with a greater amount of
that carbonate locating on the B-site. The increase in both unit cell parameters of the heated samples with increasing temperature was supportive of addition of carbonate ions in both hydroxyl and phosphate sites, but the unit cell parameter changes could also be associated with the reduction in the hydroxyl and HPO$_4$ peak intensities observed in the FTIR data, and/or rearrangement of the planar carbonate groups on their respective sites, as the samples are heated. The heated samples do not significantly improve the crystallinity of the samples, with temperatures above 750°C typically required to achieve this, which limits the analysis of the structure by Rietveld refinement of the diffraction data.

4. Conclusions

K–CO$_3$ co-substituted apatite materials with potassium and carbonate contents that ranged from approximately 0.4–0.9 wt% and 3.4–13.0 wt% respectively were prepared by aqueous precipitation reaction between Ca(OH)$_2$, H$_3$PO$_4$, and either K$_2$CO$_3$ or KHCO$_3$. A subsequent heat treatment in dry CO$_2$ at 600°C allowed for a potassium–carbonate co-substituted apatite containing approximately 16.9 wt% CO$_3^{2−}$ to be prepared, believed to be amongst the largest carbonate contents that have been reported for such a material to date. Dissolution experiments showed that the solubility of these materials increased with increasing potassium/carbo
date substitution. Whilst this work demonstrates that K–CO$_3$ co-substituted apatites with high levels of carbonate incorporation can be prepared using simple, room temperature, aqueous precipitation reactions with starting reagents unlikely to pose significant environmental risks, comprehensive testing of these materials in prospective applications (e.g. as solid fertilisers) would be required before they can be considered a viable CO$_2$ utilisation option.

Conflicts of interest
