Running headline: Nonbreeders and population growth

*lee@alumni.ntnu.no

Summary

1. Adult individuals that do not breed in a given year occur in a wide range of natural populations. However, such nonbreeders are often ignored in theoretical and empirical population studies, limiting our knowledge of how nonbreeders affect realized and estimated population dynamics and potentially impeding projection of deterministic and stochastic population growth rates.
2. We present and analyze a general modeling framework for systems where breeders and nonbreeders differ in key demographic rates, incorporating different forms of nonbreeding, different life histories, and frequency-dependent effects of nonbreeders on demographic rates of breeders.
3. Comparisons of estimates of deterministic population growth rate, λ , and demographic variance, σ_d^2 , from models with and without distinct nonbreeder classes show that models that do not explicitly incorporate nonbreeders give upwardly biased estimates of σ_d^2 , particularly when the equilibrium ratio of nonbreeders to breeders, N_{nb}^*/N_b^* , is high. Estimates of λ from empirical observations of breeders only are substantially inflated when individuals frequently re-enter the breeding population after periods of nonbreeding.
4. Sensitivity analyses of diverse parameterizations of our model framework, with and without negative frequency-dependent effects of nonbreeders on breeder demographic rates, show how changes in demographic rates of breeders versus nonbreeders differentially affect λ . In particular, λ is most sensitive to nonbreeder parameters in long-lived species, when $N_{nb}^*/N_b^* > 0$, and when

individuals are unlikely to breed at several consecutive time steps.

5. Our results demonstrate that failing to account for nonbreeders in population studies can obscure low population growth rates that should cause management concern. Quantifying the size and demography of the nonbreeding section of populations and modeling appropriate demographic structuring is therefore essential to evaluate nonbreeders' influence on deterministic and stochastic population dynamics.

demographic stochasticity, floaters, intermittent breeding, matrix model, non-breeding, population dynamics, reproductive skipping, sensitivity analysis

Introduction

1 Nonbreeders, here defined as sexually mature individuals that do not breed in a
2 given breeding season, occur in numerous populations of diverse animal taxa, span-
3 ning reptiles (e.g., Olsson & Shine, 1999), mammals (e.g., Beauplet *et al.*, 2006),
4 fish (e.g., Moore *et al.*, 2013), and birds, in which they seem to be particularly
5 common (e.g., Newton, 1998; Cam *et al.*, 1998; Renton, 2004). Demography (sur-
6 vival and future breeding), age structure, environmental stochasticity experienced,
7 and interactions with or effects on conspecifics might differ substantially between
8 breeding and nonbreeding segments of a population, for example due to different
9 habitat selection and space use (e.g., Sandercock *et al.*, 2000; Renton, 2004; Beau-
10 plet *et al.*, 2006; Campioni *et al.*, 2012). However, little is known about how the

11 presence of nonbreeders might alter projections of future population growth and
12 extinction risk. Can models that do not explicitly include demographic structure
13 caused by nonbreeders provide accurate estimates of population growth? How
14 biased are population growth rate estimates from studies of breeding segments
15 of populations when populations also contain nonbreeders? How will populations
16 respond to environmental changes that have different effects on breeders and non-
17 breeders?

18 Population growth consists of deterministic and stochastic elements. The de-
19 terministic growth rate, λ , quantifies expected population growth. The realized
20 stochastic population growth rate is usually lower than λ , due to effects of envi-
21 ronmental and demographic stochasticity (Lande, Engen & Sæther, 2003). De-
22 mographic stochasticity describes variation among individuals caused by chance
23 realizations of survival and fecundity (May, 1973) and can be quite influential
24 in small populations, where it tends to increase extinction risk (Lande, Engen
25 & Sæther, 2003). Accurate estimates of stochastic population growth in small
26 populations therefore require estimation of both λ and the demographic variance,
27 σ_d^2 .

28 Standard Leslie matrix models (Leslie, 1945) explicitly account for age struc-
29 ture, but not other forms of demographic structure. In these commonly used
30 models, nonbreeders are simply represented by zeros in the estimated distribution
31 of offspring production (equal to failed breeders). Estimation of the demographic
32 variance, σ_d^2 , then requires knowledge of the distribution of offspring production in
33 the population, as well as any covariance between survival and reproduction (En-
34 gen *et al.*, 2009), such as that caused by consistent differences in survival between
35 breeders and nonbreeders. Additionally, persistent differences among individuals

36 in their propensity to breed create another source of covariation that cannot easily
37 be accounted for within the basic Leslie matrix framework.

38 Alternatively, breeders and nonbreeders can be modeled in separate classes
39 with distinct demographic rates. This is a straightforward way to account for
40 demographic differences between breeders and nonbreeders and the resulting co-
41 variances, but it increases the number of parameters that need to be estimated
42 from population data. Such models have been mostly restricted to studies of long-
43 lived seabirds, parrots and plants (e.g. Werner & Caswell, 1977; Jenouvrier *et al.*,
44 2005; Beissinger *et al.*, 2008; Gremer, Crone & Lesica, 2012; Waugh *et al.*, 2015).
45 To reduce bias in projections of future population growth we must determine when
46 the more complex model structures should be used, by quantifying differences in
47 estimates of λ and σ_d^2 obtained from models with different structures.

48 Accurate predictions from population projection models also require accurate
49 estimates of demographic rates. Nonbreeders are often harder to detect than breed-
50 ers (Pardo *et al.*, 2013), particularly because population studies tend to focus
51 on breeders and the areas they occupy (Katzner *et al.*, 2011b). For example, a
52 common practice for studying breeding bird populations is to search for nests,
53 color-ring offspring and catch or resight adults at the nests without concurrent
54 resighting of nonbreeders (e.g. Keyser, 2004; Gruebler *et al.*, 2008; Mounce *et al.*,
55 2013). Fecundity estimates from the observed breeders are then combined with
56 survival estimates from resighting data, implicitly assuming that surviving individ-
57 uals breed at all time steps, even when not observed. An important step to avoid
58 biased estimates of population growth is to test how this assumption affects the
59 accuracy of population growth estimates when populations contain nonbreeders.

60 In addition to understanding how the presence of nonbreeders affects estimates

61 of population growth and demographic variance, quantifying the role of nonbreed-
62 ers in actual population dynamics can be crucial to projecting population responses
63 to environmental change. Breeders and different types of nonbreeders might re-
64 spond differently to changes, either because they utilize different areas and re-
65 sources (Caro, Ontiveros & Pleguezuelos, 2011; Campioni *et al.*, 2012), or because
66 conservation efforts are directed at one group more than the other. For example,
67 conservation efforts that improve access to resources used by breeders might have
68 no effect on nonbreeders, whereas habitat destruction in areas used by nonbreeders
69 might have severe negative impacts on population dynamics without influencing
70 breeders directly. Despite the prevalence of nonbreeders in natural populations,
71 we currently lack a general framework for evaluating the potential impact of differ-
72 ent types of nonbreeders on population dynamics and responses to change. Such
73 a framework must incorporate population structure caused by different types of
74 nonbreeders with different demographic rates, such as young individuals that have
75 not yet entered the breeding population (sometimes referred to as prebreeders; e.g.,
76 Jenouvrier *et al.*, 2008); nonbreeders that have bred previously but are currently
77 skipping a year (experienced nonbreeders; e.g., Cubaynes *et al.*, 2011); and old
78 nonbreeders that are unlikely to acquire the resources needed for further breeding
79 (senescent nonbreeders, e.g., Olesiuk, Bigg & Ellis, 1990).

80 Population responses to environmental change might also depend on interac-
81 tions between individuals. In addition to potential contributions to future breed-
82 ing, nonbreeders can have negative or positive effects on current breeding through
83 competition (Carrete, Donázar & Margalida, 2006), harassment and infanticide
84 (Bonebrake & Beissinger, 2010) or helping behavior (Reyer, 1990). Negative ef-
85 fects of nonbreeders can take two forms. By increasing the total population size,

86 nonbreeders contribute to density dependence in much the same way that breed-
87 ers do (Wauters & Lens, 1995; Carrete, Donázar & Margalida, 2006). In addition,
88 when nonbreeders interfere with breeding, for example by harassing breeders or
89 forcing territory defence, frequency dependence can arise, in which breeder sur-
90 vival or fecundity is reduced when the ratio of nonbreeders to breeders becomes
91 high (Wauters & Lens, 1995; Newton & Rothery, 2001). If such frequency depen-
92 dence influences population dynamics, models projecting population responses to
93 environmental change must also incorporate these effects.

94 We present a general framework of population projection models that explic-
95 itly incorporate various types of nonbreeders. We compare estimates of λ and σ_d^2
96 from these models to those from standard Leslie matrix models without distinct
97 nonbreeder classes to determine whether differences in model structure are likely
98 to bias estimates of population growth ("Model structure analysis"). We then
99 quantify the bias caused by estimating λ from observations of breeders only ("Ob-
100 servation analysis"). Using a wide range of biologically realistic parameterizations
101 within our model framework, we analyze the sensitivity of λ to changes in the
102 demographic rates of breeders and nonbreeders in systems with different types of
103 nonbreeders, and test how frequency-dependent effects of nonbreeders on breeder
104 survival and fecundity alter the responses of λ to demographic changes ("Sensi-
105 tivity analysis"). Thus, we establish how the often disregarded nonbreeders affect
106 both population growth itself and our estimates of such growth.

107 **Materials and methods**

108 **Classification and modeling of nonbreeder systems**

109 Nonbreeding individuals have been referred to as floaters (Brown, 1969; Lenda,
110 Maciusik & Skorka, 2012), intermittent breeders (Calladine & Harris, 1997), non-
111 breeders (Cam *et al.*, 1998), and non-nesters (Moynahan, Lindberg & Thomas,
112 2006), with different connotations. Here, we define nonbreeders as individuals
113 that are sexually mature but do not initiate breeding in a given breeding season.

114 We classify systems with nonbreeders by five characteristics: types of distinct
115 nonbreeder classes (Fig. 1a,b); age structure (Fig. 1c); presence of senescent indi-
116 viduals (Fig. 1d); effect on breeding probability of recent breeding history (Fig. 1e);
117 and age at maturity (Fig. 1f). Figure 1 demonstrates how each of these charac-
118 teristics can be described by life cycle graphs that translate into single-sex matrix
119 models. Combining subsets of these life cycles according to the characteristics of
120 individual systems provides the flexibility to build appropriate matrix models for
121 a wide range of populations.

122 In contrast to standard Leslie matrix models (Leslie, 1945) in which individ-
123 uals are separated only into age classes, our models distinguish nonbreeders from
124 breeders (Fig. 1a). In some cases, nonbreeders can be further separated into dis-
125 tinct classes that differ in their probabilities of surviving or of becoming breeders.
126 For brevity we only analyze the common case where inexperienced nonbreeders
127 (i.e., individuals that are sexually mature but have not yet bred) have a lower
128 probability of surviving and of breeding at the next time step than experienced
129 nonbreeders that have bred previously (Fig. 1b), as in kittiwakes (*Rissa tridactyla*;
130 Cam *et al.*, 1998; Desprez *et al.*, 2011). Systems with other configurations of sur-

131 vival and breeding probability can be analyzed in the same way using the R code
132 (R Core Team, 2014) provided in Appendix S2 and S3.

133 Age is an important factor in determining breeding probability and survival
134 in many species, and can have different effects in breeders and nonbreeders (e.g.,
135 in subantarctic fur seals (*Arctocephalus tropicalis*), Beuplet *et al.*, 2006). Age-
136 structured models with nonbreeders are then appropriate (Fig. 1c). One specific
137 type of age structure is caused by senescent individuals that are too old to breed
138 but are still alive (Fig. 1d). For example, in killer whales (*Orcinus orca*) females
139 stop reproducing around age 40, but have a mean life expectancy of 50 years (max.
140 90 years; Olesiuk, Bigg & Ellis, 1990; Brent *et al.*, 2015). Such a postreproductive
141 class does not contribute directly to population growth, but can still have indirect
142 effects through (positive or negative) frequency or density dependence.

143 Finally, the probability of an individual breeding at a given time step can be
144 influenced by its recent reproductive history (Fig. 1e). For example, if breeding
145 is costly, breeding probability might decrease directly after a breeding event (or
146 after several successive breeding events), whereas individuals that have not bred
147 for a year or two gain a higher breeding probability. For example, female southern
148 snow skinks (*Niveoscincus microlepidotus*) never breed two years in a row, and
149 often skip two seasons before reproducing a second time (Olsson & Shine, 1999).

150 Age at maturity, a_m , is the first age at which individuals are physiologically
151 mature and could breed. For example, small primates, such as galagos (Galagidae),
152 can usually breed at age one, whereas chimpanzees (*Pan troglodytes*) do not reach
153 maturity until age ten (Harvey & Clutton-Brock, 1985). In all our models, the
154 parameter a_m determines the number of immature age classes present in the life
155 cycle (Fig. 1f, Figs 1a-e are shown with $a_m = 2$).

156 The life cycles shown in Fig. 1 are special cases of a broad spectrum of systems,
157 and are not mutually exclusive. For example, immatures, different types of non-
158 breeders, and various forms of age structure can co-occur. The life cycles in Fig. 1
159 can be rearranged and used as building blocks to model most nonbreeder systems.
160 Matrices for each life cycle can be constructed assuming either pre-breeding or
161 post-breeding census. With post-breeding census there is an additional class of
162 newborns in each case. Appendix S1 provides pre-breeding census matrices for
163 each life cycle in Fig. 1, with examples of how to construct corresponding post-
164 breeding census matrices. R code (R Core Team, 2014) for constructing matrices
165 of either type and analyzing them is available in Appendix S2 and S3.

166 All our analyses utilize parameterizations of the life cycles in Fig. 1, selected
167 to represent a range of biologically representative systems with different types of
168 nonbreeder structure (Table S1). Survival probabilities and age at maturity are
169 chosen to represent long-lived, "slow" species (high survival, medium age at ma-
170 turity) and short-lived, "fast" species (low survival, low age at maturity). In most
171 systems analyzed, nonbreeders are assumed to have lower probabilities of surviving
172 and of breeding at the next time step than breeders, but we also consider systems
173 where nonbreeders and breeders have the same demographic rates, or where breed-
174 ers have lower survival and future breeding probabilities than nonbreeders. The
175 latter case might represent situations where breeding is costly. Table S1 gives an
176 overview of which systems are used in each analysis. All parameters are reported
177 in tables S2 and S3.

178 **Model structure analysis**

179 For a range of systems with nonbreeders, estimates of stochastic population growth
180 parameters λ and σ_d^2 from our pre-breeding census population projection models
181 with separate breeder and nonbreeder classes were compared to estimates from
182 Leslie matrix models of the same systems without separate nonbreeder classes.
183 Systems representing several different types of nonbreeder structure and life his-
184 tory "speed" were considered (Tables S1-S3). Fecundity (defined as the number
185 of female offspring produced per female that survive to age 1) was set so that
186 $\lambda = 1 \pm 0.00005$. Most analyzed parameter sets resulted in populations with fewer
187 nonbreeders than breeders at equilibrium ($N_{nb}^* < N_b^*$; Tables S2 and S3). To evalu-
188 ate the importance of the N_{nb}^*/N_b^* ratio, we also analyzed "breeding status" systems
189 with more nonbreeders than breeders at equilibrium ($N_{nb}^*/N_b^* > 1$) and with equal
190 numbers ($N_{nb}^*/N_b^* = 1$). In the latter case nonbreeder survival probability was
191 set either equal to or greater than breeder survival probability (Table S2). Leslie
192 matrices were parameterized by calculating demographic parameters for each age
193 as the average of breeder and nonbreeder parameters, weighted by stable stage
194 structure. This equates to classifying nonbreeders as failed breeders. In "breeding
195 experience" (Fig. 1b) and "recent breeding history" (Fig. 1e) systems, where age is
196 not part of the nonbreeding structure, parameterization of Leslie matrices entailed
197 first analyzing an expanded matrix with both breeding status and age structure,
198 to find appropriate weights. The number of age classes in the Leslie model was
199 set equal to the sum of breeder and nonbreeder classes in the non-age-structured
200 models. For comparison, we also analyzed a Leslie matrix with only one adult
201 age class. The demographic variance was calculated from the matrices using the

202 method described in Engen *et al.* (2009), and covariances between survival and
203 fecundity were accounted for in calculations from Leslie matrices (Engen *et al.*,
204 2009).

205 **Observation analysis**

206 To quantify bias caused by the common practice of estimating λ based on observa-
207 tions of breeding segments of populations only, estimates of λ from "age structure"
208 models (Fig. 1c) parameterized with full data on both nonbreeders and breeders
209 versus data on only the breeding population were compared. For simplicity, the
210 breeders only case assumed that all breeders and offspring were observed and
211 marked, whereas nonbreeders were not observed. Thus, all individuals that bred
212 at a given age affected survival estimates for all preceding ages (whether they bred
213 previously or not), while fecundity estimates were based only on breeders. Since
214 complete detection of offspring in a system with unobserved nonbreeders is most
215 likely when the population is censused directly after breeding, post-breeding cen-
216 sus matrices were used for this analysis. The assumption that all offspring were
217 observed allowed estimated survival probabilities to be calculated directly from
218 the model parameters. For each age class, a , the probability of an individual being
219 alive and breeding at this or future ages was calculated. This was achieved by cal-
220 culating probabilities of each path through the life cycle, adding the probabilities
221 for all paths leading to breeding at age a , and all paths in which individuals were
222 nonbreeders at age a but breeders at a later age. This gave estimated survival up
223 to the focal age a . Dividing this probability by the estimated survival probability
224 found for age $a - 1$ yielded the survival probability from age $a - 1$ to a . We set

225 a maximum lifespan, making the analyzed system a variant of Fig. 1c, without
226 self-loops for the last age classes. Underlying probabilities of survival and breed-
227 ing were set equal for all age classes. We quantified how the difference between
228 estimates of λ from the full model versus the model that ignored nonbreeders
229 was influenced by nonbreeder survival, transition probabilities from nonbreeder to
230 breeder, and maximum lifespan.

231 **Sensitivity analyses**

232 Sensitivity analyses were used to quantify how changes in the demographic rates
233 of breeders and nonbreeders are expected to affect λ in systems with different
234 types of nonbreeders. Each life cycle presented in Fig. 1 was analyzed, with pa-
235 rameters covering the same range of biologically representative systems as for the
236 Model Structure Analysis (Tables S2 and S3). Fecundity was again set such that
237 $\lambda = 1 \pm 0.00005$. For each pre-breeding census system we performed numerical sen-
238 sitivity analysis using a finite difference approximation with $\Delta = 0.005$ and scaled
239 the result to a unit change in each parameter. This is equivalent to a standard
240 sensitivity analysis focused on lower-level parameters (Caswell, 2001) but is easier
241 to implement in frequency-dependent systems. R code is provided in Appendix S2
242 and S3, including code for performing standard lower-level sensitivity analysis for
243 comparison.

244 Effects of negative frequency dependence were quantified by letting breeder
245 survival or fecundity depend on the ratio of nonbreeders to breeders. In the former
246 case, realized breeder survival was calculated as $s_b / (1 + \frac{N_{nb}}{N_b})$, where s_b is the
247 breeder survival in the absence of nonbreeders, and N_{nb} and N_b are the numbers of

248 nonbreeders and breeders in the population at a given time step. Similarly, when
249 fecundity was frequency dependent, realized fecundity was $f/(1 + \frac{N_{nb}}{N_b})$, where f is
250 fecundity in the absence of nonbreeders. The sensitivity analysis performed on the
251 frequency-independent systems was repeated for each of the frequency-dependent
252 systems. The deterministic growth rate, λ , was calculated by projecting each
253 model over time until an equilibrium proportional population structure, \hat{n} , was
254 reached, satisfying $\hat{n} = \frac{A[\theta, \hat{n}]\hat{n}}{\|A[\theta, \hat{n}]\hat{n}\|}$, where A is the population projection matrix, θ
255 represents the matrix parameters, and $\|A[\theta, \hat{n}]\hat{n}\|$ is the one-norm of $A[\theta, \hat{n}]\hat{n}$ (i.e.,
256 the sum of the absolute values of its components, Caswell, 2001, 2008). At this
257 equilibrium, populations grow exponentially at a rate λ given by the dominant
258 eigenvalue of $A[\theta, \hat{n}]$. All systems analyzed reached such an equilibrium.

259 Results

260 Model structure analysis

261 Leslie matrix models without separate nonbreeder classes, that implicitly classify
262 nonbreeders as failed breeders, gave identical estimates of λ as models with separate
263 nonbreeder classes. However, models without separate nonbreeder classes gave
264 higher estimates of σ_d^2 (Table 1). The greatest proportional differences occurred
265 in the "breeding status" system when the equilibrium ratio of nonbreeders to
266 breeders (N_{nb}^*/N_b^*) exceeded one, followed by systems where $N_{nb}^*/N_b^* = 1$. When
267 $N_{nb}^*/N_b^* < 1$, the "recent breeding history" and the "breeding experience system"
268 without adult age structure had the greatest proportional differences in estimated
269 σ_d^2 . In the "recent breeding history" system, adding adult age structure to the

270 model without separate nonbreeder classes increased the difference in σ_d^2 (Table 1).
271 "Breeding status" systems with $N_{nb}^*/N_b^* < 1$ and slow life-histories showed very
272 small differences in estimated σ_d^2 .

273 **Observation analysis**

274 As expected, using demographic estimates from observations of only the breeding
275 population caused λ to be overestimated (Fig. 2). The bias in λ was large in many
276 cases, and increased with increasing breeder survival probability, with increasing
277 maximum lifespan, and with increasing transition probability from nonbreeder to
278 breeder.

279 **Sensitivity analysis**

280 In frequency-independent systems, the sensitivity of λ to survival probabilities de-
281 pended on N_{nb}^*/N_b^* . When $N_{nb}^*/N_b^* < 1$, λ was typically more sensitive to small
282 changes in breeder survival probability, s_b , than to small changes in survival prob-
283 abilities of nonbreeders, s_{nb} , or immatures, s_{im} , or to small changes in breeding
284 probabilities (i.e., probabilities of transitioning to or staying in the breeder class;
285 b_{am} , b_{nb} , b_b) (Figs 3 and 4, gray bar to left of dashed line). Conversely, when
286 $N_{nb}^*/N_b^* > 1$, λ was more sensitive to s_{nb} than to any other parameter (Fig. 5a,
287 black bar to left of dashed line). Finally, when $N_{nb}^*/N_b^* = 1$, λ was equally sensitive
288 to s_{nb} and s_b (Fig. 5b, c, gray and black bars to left of dashed line).

289 In general, the relative sensitivity of λ to breeding probabilities versus survival
290 probabilities was higher in systems representing short-lived species than in systems
291 representing long-lived species (Fig. 3, compare bars on each side of dashed line).

292 The relative sensitivity to breeding probabilities compared to survival probabili-
 293 ties was also highest in systems where nonbreeders had lower demographic rates
 294 than breeders ($s_{nb}, b_{nb} < s_b, b_b$), and lowest in systems where breeding was "costly"
 295 ($s_{nb}, b_{nb} > s_b, b_b$) (Fig. 3, top and bottom panels). The sensitivity of λ to s_{im} de-
 296 pended on fecundity rates, with higher sensitivity in systems with higher fecundity
 297 (e.g. Figs 3a, 4c, white bar to left of dashed line).

298 Overall, in long-lived species, s_{nb} was one of the demographic parameters to
 299 which λ was the most sensitive, even when $N_{nb}^*/N_b^* < 1$ (Fig. 3, left column
 300 of panels, black bar to left of dashed line). The absolute sensitivity to s_{nb} was
 301 similar in short-lived and long-lived species, but λ was more sensitive to breeding
 302 probabilities in short-lived species. This caused s_{nb} to be one of the demographic
 303 parameters to which λ was the least sensitive in short-lived species when $N_{nb}^*/N_b^* <$
 304 1 (Fig. 3, right column of panels, black bar to left of dashed line). The exception
 305 was the system with "costly" breeding, where λ was less sensitive to breeding
 306 probabilities than to s_{nb} even in the short-lived species (Fig. 3, right bottom panel,
 307 black bar to left of dashed line). In the "recent breeding history" system, λ was
 308 slightly more sensitive to s_{nb} than to s_b (Fig. 4d).

309 The sensitivity of λ to breeding probabilities of newly mature individuals or
 310 breeders (b_{am}, b_b) was generally quite high in short-lived species (Fig. 3, right
 311 column; Fig. 5, white and gray bar to right of dashed line), particularly when
 312 nonbreeders had lower survival and breeding probability than breeders (Fig. 3d).
 313 The sensitivity of λ to breeding probability of nonbreeders, b_{nb} was low in all
 314 frequency-independent systems with $N_{nb}^*/N_b^* < 1$ (Figs 3 and 4, black bars to
 315 right of dashed line). However, when $N_{nb}^*/N_b^* > 1$, λ was more sensitive to b_{nb}
 316 than to b_b . When $N_{nb}^*/N_b^* = 1$, the sensitivity of λ to b_{nb} and b_b was determined

317 by the survival probabilities. Thus, when $s_{nb} = s_b$, λ was equally sensitive to b_{nb}
318 and b_b (Fig. 5b, gray and black bars to right of dashed line), whereas $s_{nb} > s_b$
319 caused λ to be more sensitive to b_{nb} than to b_b (Fig. 5c, gray and black bars to
320 right of dashed line).

321 With frequency dependence in the form of a negative effect of nonbreeders on
322 breeder survival, λ generally became less sensitive to s_b , and more sensitive to
323 b_{im} and b_{nb} (compare top row of Fig. 6 to Figs 3a, 3d, 4a, 4c). In the “breed-
324 ing experience” system (Fig. 1b), frequency dependence in survival increased the
325 sensitivity of λ to the demographic parameters of inexperienced breeders (Fig. 6e,
326 black bars). When fecundity was frequency dependent, λ became slightly more
327 sensitive to breeding probabilities (particularly in short-lived species), but sensi-
328 tivity to survival probabilities changed little (compare bottom row of Fig. 6 to
329 Figs 3a, 3d, 4a, 4c). Both types of frequency dependence caused the sensitivity of
330 λ to the survival probability of senescent nonbreeders to become negative (i.e., an
331 increase in survival of senescent nonbreeders caused a decrease in λ ; hatched bars
332 in Fig. 6g, h).

333 Discussion

334 Nonbreeders of various forms are common in nature and could substantially im-
335 pact population demography, dynamics and responses to environmental change,
336 thus playing a crucial role in determining the stability and viability of animal
337 populations. However, nonbreeders are surprisingly often ignored in both theoret-
338 ical and empirical studies of population dynamics. Here, we defined a conceptual
339 framework for modeling systems with different types of nonbreeders and quantify-

340 ing their effects on population growth. Parameterizations for diverse representative
341 life-histories demonstrate the potential major effects of failing to account for non-
342 breeders when estimating current and future population growth, and demonstrate
343 the influence of model structure on estimates of stochastic population dynamics.

344 **Model structure analysis**

345 The observation that matrix models with distinct nonbreeder classes give identi-
346 cal estimates of λ as a simpler Leslie matrix model with breeders and nonbreeders
347 combined in the same class(es) is expected, since λ is estimated from mean survival
348 and fecundity rates, which do not differ between the two models. However, Leslie
349 matrix models tended to give higher estimates of σ_d^2 than models with separate
350 nonbreeder classes (Table 1). This is because Leslie matrix models treat systematic
351 or structured variation in demographic rates among same-aged breeders and non-
352 breeders as random variation among average individuals, whereas such structured
353 variation actually decreases the demographic variance compared to that found in
354 a homogeneous population ("variance reduction effect", Fox & Kendall, 2002).
355 This effect was most marked when there was a high proportion of nonbreeders in
356 the equilibrium population ($N_{nb}^*/N_b^* \geq 1$) which exaggerates the "zero inflation" of
357 the offspring production distribution caused by nonbreeder population structure.
358 In systems with lower equilibrium proportions of nonbreeders, the differences in
359 estimates of σ_d^2 between the two models were quite small (Table 1). Thus, census-
360 ing the nonbreeding segments of populations is crucial for evaluating the impact of
361 model structure on estimates of σ_d^2 in wild populations. Unfortunately, nonbreeder
362 censusing is rarely considered in current monitoring programs (Citta, Reynolds &

363 Seavy, 2007; Rönkä *et al.*, 2011; Baasch, Hefley & Cahis, 2015).

364 When survival probability differs among breeders and nonbreeders, some of the
365 systematic demographic variation caused by the presence of nonbreeders appears
366 as a covariance between survival and reproduction. This covariance can be ac-
367 counted for in the model without separate nonbreeder classes, thus decreasing the
368 discrepancy between estimates of σ_d^2 in the two models (e.g., compare lines 8 and
369 9 of "breeding status" models in Table 1). When nonbreeding is correlated with
370 age, as in the "breeding experience" system, much of the demographic structure
371 is captured by purely age-structured models ("breeding experience" system with
372 3 adult age classes, Table 1). When all adults are placed in a single age class, this
373 demographic structure is no longer directly accounted for, causing higher estimates
374 of σ_d^2 ("breeding experience" system with 1 adult age class, Table 1). Conversely,
375 the structure in the "recent breeding history" system is not closely correlated with
376 age. Therefore, in this system, adding adult age structure caused the estimated σ_d^2
377 to deviate more from that estimated in the model with separate nonbreeder classes
378 ($\sigma_{d_nb}^2$) ("recent breeding history" system with 6 age classes compared to with 1
379 age class, Table 1). Thus, it is not model structure per se that is important, but
380 how well the structure accounts for demographic heterogeneity.

381 Modern mark-recapture methods facilitate identification of population struc-
382 tures other than age that explain heterogeneity in demographic rates (e.g. Pradel,
383 Choquet & Béchet, 2012). In nature, nonbreeders are often harder to detect than
384 breeders (e.g. Sandercock *et al.*, 2000; Katzner *et al.*, 2011a; Pardo *et al.*, 2013).
385 Using mark-recapture models that account for such differences in detection prob-
386 ability is essential to avoid bias in estimates of demographic rates, and a natural
387 next step is to test whether the demographic rates of breeders and nonbreeders

388 differ. If they do, the life cycles shown in Fig. 1 might be more appropriate repre-
389 sentations of the systems than pure age structure.

390 **Observation analysis**

391 Accounting for demographic differences between breeders and nonbreeders is clearly
392 important for estimating population growth rates, but what happens if the pres-
393 ence of nonbreeders is unknown or ignored? The common practice of estimating
394 demographic parameters and growth rates based solely on the breeding popula-
395 tion (Grüebler *et al.*, 2008; Katzner *et al.*, 2011b; Chastant *et al.*, 2014) results
396 in potentially large overestimates of λ when the population contains nonbreed-
397 ers (Fig. 2). This is because estimating fecundity from only breeders invokes an
398 implicit assumption that all surviving individuals breed at all time steps. Since
399 individuals observed as breeders after a period of nonbreeding contribute to sur-
400 vival estimates, estimates of λ are inflated. This situation can easily arise when
401 survival and fecundity are estimated separately, for example when survival esti-
402 mates from published mark-recapture studies are paired with fecundity estimates
403 from breeders (as in Mounce *et al.*, 2013). The same type of overestimation of λ
404 has been demonstrated when unproductive females are excluded from estimated
405 maternity rates in large carnivores (Chapron, Wielgus & Lambert, 2013).

406 Such overestimation of λ arose in all systems studied, but to varying degrees.
407 The most extreme bias was found when nonbreeder survival probability was high,
408 when maximum lifespan was high, and when nonbreeders had a high probability of
409 becoming breeders at a future time step (Fig. 2). This is because all these factors
410 increase the proportion of nonbreeders that survive and later (re-)enter the breed-

411 ing population. When only breeding individuals are observed, only nonbreeders
412 that (re-)enter the breeding population contribute to the overestimation of λ . In
413 fact, if nonbreeding were permanent, λ could be accurately estimated from the
414 breeding population. This overestimation of λ can be partially rectified by using
415 mark-recapture methods that estimate the probability of an individual being a
416 first-time breeder (Pradel, 1996). However, this method only considers inexperi-
417 enced nonbreeders, not individuals that skip a year after having bred previously.
418 Nonbreeders that *are* observed during the breeding season can help improve esti-
419 mates of λ if they are included in the fecundity estimates. We suggest that the best
420 way to avoid biased estimates of λ when the presence of nonbreeders is unknown is
421 to report estimates of λ as a range of values with the lower limit calculated under
422 the assumption that all undetected individuals are nonbreeders, and the upper
423 limit under the assumption that they are all breeders.

424 **Sensitivity analysis**

425 Accurately predicting population responses to changes in various demographic
426 rates can be crucial for population management, yet sensitivities of λ to non-
427 breeder parameters are rarely considered. Our analyses of systems incorporating
428 different types of nonbreeders showed that the relative sensitivity of λ to survival
429 and breeding probability of breeders and nonbreeders depended on several factors.
430 The equilibrium ratio between nonbreeders and breeders, N_{nb}^*/N_b^* , was central. λ
431 was most sensitive to change in the survival probability of nonbreeders, s_{nb} , when
432 there was a high proportion of nonbreeders in the population (Fig. 5), and indeed
433 was more sensitive to s_{nb} than to any other parameter in such systems (Fig. 5).

434 Conversely, when there were more breeders than nonbreeders in the population at
435 equilibrium, λ was more sensitive to breeder survival than to any other parameter.
436 This further highlights the need to collect sufficient data on the nonbreeding seg-
437 ments of populations to evaluate the ratio, N_{nb}^*/N_b^* . However, showing that there
438 are more breeders than nonbreeders in a population does not mean that nonbreed-
439 ers can safely be ignored. In long-lived species with $N_{nb}^*/N_b^* < 1$, nonbreeder
440 survival was still one of the parameters to which population growth rate was the
441 most sensitive. In such species, protecting nonbreeders could therefore be expected
442 to increase population growth more than facilitating higher breeding probabilities.
443 Conversely, in short-lived species, improving conditions for early recruitment into
444 the breeding population and repeat breeding across time steps would be expected
445 to increase λ more than improving nonbreeder survival (except when breeding is
446 "costly"). But since the absolute sensitivity of λ to s_{nb} is similar in short- and
447 long-lived species, changes that decrease nonbreeder survival would cause similar
448 changes in λ in both systems. If only breeders are monitored, changes in mor-
449 tality rates of nonbreeders might initially go undetected, potentially preventing
450 appropriate conservation actions from being implemented (Kenward *et al.*, 2000;
451 Penteriani *et al.*, 2005).

452 Population growth rate was also particularly sensitive to changes in nonbreeder
453 survival probability when individuals were unlikely to breed in many consecutive
454 time steps, but rather tended to take years off between breeding events ("Recent
455 breeding history" system, Fig. 4d). In such systems, which are quite common in
456 nature (Shaw & Levin, 2013), a high proportion of individuals will be nonbreeders
457 at some point in their life before potentially re-entering the breeding population,
458 explaining why λ would be sensitive to changes in nonbreeder survival.

459 Our analysis indicates that the transition probability from nonbreeder to breeder
460 has little effect on λ in frequency-independent systems when $N_{nb}^*/N_b^* < 1$. This is
461 particularly evident in systems with high survival, where nonbreeders are likely to
462 have multiple opportunities to become breeders. In such systems, increasing the
463 rate at which nonbreeders become breeders will have only a minor effect on the to-
464 tal number of breeders in the population. Conversely, in systems with $N_{nb}^*/N_b^* \geq 1$,
465 changes in the transition probability from nonbreeder to breeder can be expected
466 to have a substantial impact on λ , as the total number of breeders is more sensitive
467 to this transition rate.

468 The complexity of the patterns of sensitivity with life-history, system and
469 N_{nb}^*/N_b^* ratio evident in Figs 3, 4, and 5 demonstrate the need to undertake
470 an appropriate sensitivity analysis for any system of interest, rather than simply
471 relying on general patterns. We provide R code for running such analyses for a
472 wide range of systems with different types of nonbreeders and any combination of
473 parameters (Appendix S2 and S3).

474 Negative effects of nonbreeders on breeder survival or reproduction have been
475 found in several studies (Wauters & Lens, 1995; Carrete, Donázar & Margal-
476 ida, 2006). This can happen when nonbreeders spend time at breeding areas
477 and attempt to oust breeders from their territories or breeding sites (Bretagnolle,
478 Mougeot & Thibault, 2008; Bonebrake & Beissinger, 2010), and when they share
479 foraging areas away from the breeding grounds (Carrete, Donázar & Margalida,
480 2006). Frequency dependence, in which breeder survival or fecundity is reduced
481 when the ratio of nonbreeders to breeders is high, can then emerge. Our analy-
482 ses show that such frequency-dependent effects of nonbreeders on breeder survival
483 changed the relative influence of demographic parameters on λ . Specifically, λ

484 became less sensitive to changes in breeder survival, since frequency-dependence
485 caused realized s_b to be lower than the baseline s_b . Sensitivity to transition prob-
486 abilities from juvenile or nonbreeder to breeder became higher, as any increase in
487 these rates helped to decrease the negative frequency-dependent effects (for exam-
488 ple, if individuals that breed are less likely to harass other breeders). Frequency
489 dependence in fecundity had little effect on sensitivities, except that sensitivity to
490 the probability of remaining in the breeding class increased.

491 These results highlight the need to consider social interactions within popula-
492 tions when selecting an appropriate focus for conservation efforts. However, they
493 also demonstrate that, in the absence of information about social interactions,
494 decisions based on frequency-independent systems and models are unlikely to be
495 highly inappropriate in frequency-dependent systems. Our models and code can
496 be used to evaluate the potential influence of unknown frequency dependence in
497 specific systems by running models with different levels of suspected interactions
498 and comparing them to models without such effects.

499 **Further nonbreeder systems**

500 Nonbreeders can also occur in and affect population dynamics of systems quite
501 different from the ones we have modeled. One type of nonbreeder that has been the
502 focus of much research is helpers in species with cooperative breeding (e.g. Koenig
503 & Dickinson, 2004; Lukas & Clutton-Brock, 2012; Paquet *et al.*, 2015). In contrast
504 to the negative frequency-dependent effects of nonbreeders in our models, helpers
505 have positive effects on breeding. Cooperative breeding and helping behavior is
506 often closely linked with family structure and kinship, prompting different types

507 of models and questions than ours (Hatchwell, 2009; McLeod & Wild, 2013).

508 When the presence of nonbreeders is directly determined by a limited num-
509 ber of territories or breeding sites, population dynamics are expected to differ
510 from those studied here (Kokko & Sutherland, 1998; Durell & Clarke, 2004). One
511 potentially important role of nonbreeders in this type of system is to buffer pop-
512 ulations against extinction from sudden environmental events (Penteriani *et al.*,
513 2005). If nonbreeders experience different environmental conditions from those
514 affecting the breeding component of a population, they can function as a pool of
515 individuals ready to move in and replace lost breeders (Penteriani *et al.*, 2005),
516 thus buffering the population against sudden loss. This means that the nonbreeder
517 to breeder transition probability varies with the number of breeders present in the
518 population. Penteriani, Otalora & Ferrer (2008) showed that increased nonbreeder
519 mortality in such systems can cause an Allee effect.

520 In some systems mate limitation is the primary reason for the presence of non-
521 breeders. The single-sex matrix models used here model an individual's breeding
522 status at a given time as the outcome of a (generalized) Bernoulli trial, and the
523 probability of moving from nonbreeder to breeder can be influenced by several fac-
524 tors, including mate availability. However, when mate limitation is the main cause
525 of nonbreeding, two-sex models are more appropriate. Analyzing two-sex models
526 in a similar framework as that presented here would be an interesting future step.

527 Populations that are large relative to their carrying capacity are often sub-
528 ject to density dependent effects as resources become limiting or negative effects
529 of crowding come into effect. Nonbreeders can contribute to these effects when
530 they compete with breeders for resources (Carrete, Donázar & Margalida, 2006).
531 Modeling the influence of nonbreeders on density-dependent dynamics is another

532 interesting next step. For example, the carrying capacity of a population might
533 be influenced by the way in which breeders and nonbreeders interact. The ratio
534 of nonbreeders to breeders, which has been suggested as a proxy for population
535 health and stability (Hunt, 1998), is also likely to be affected.

Table 1: Effects on estimates of demographic variance (σ_d^2) of pooling breeders and nonbreeders and calculating demographic parameter values from weighted averages ($\sigma_{d_est}^2$), compared to estimates from models with separate nonbreeder classes ($\sigma_{d_nb}^2$). s_b, b_b, s_{nb} and b_{nb} are survival probabilities (s) and probabilities of staying in or moving to a breeding class (b), of breeders and nonbreeders (subscripts b and nb respectively). a_m is age at maturity. N_{nb}^*/N_b^* is the equilibrium ratio of nonbreeders to breeders. Parameters are set equal to those used in systems in Figs 3 and 4. Variance in fecundity is 0.5 in all systems.

System	Figure	a_m	Survival	Nonbreeder "quality"	N_{nb}^*/N_b^*	$\sigma_{d_nb}^2$	$\Delta\sigma_{d_est}^2$
Breeding status	3a	4	High	$s_{nb}, b_{nb} < s_b, b_b$	< 1	0.266	+0.003
Breeding status	3b	4	High	$s_{nb}, b_{nb} = s_b, b_b$	< 1	0.194	+0.005
Breeding status	3c	4	High	$s_{nb}, b_{nb} > s_b, b_b$	< 1	0.183	+0.003
Breeding status	3d	1	Low	$s_{nb}, b_{nb} < s_b, b_b$	< 1	0.835	+0.012
Breeding status	3e	1	Low	$s_{nb}, b_{nb} = s_b, b_b$	< 1	0.708	+0.028
Breeding status	3f	1	Low	$s_{nb}, b_{nb} > s_b, b_b$	< 1	0.632	+0.026
Breeding status	5a	1	Low	$s_{nb} = s_b$	> 1	0.750	+0.799
Breeding status	5b	1	Low	$s_{nb} = s_b$	$= 1$	0.750	+0.250
Breeding status	5c	1	Low	$s_{nb} > s_b$	$= 1$	0.531	+0.141
Breeding experience, 1 age class	4a	2	-	$s_{nb}, b_{nb} < s_b, b_b$	< 1	0.314	+0.042
Breeding experience, 3 age classes	4a	2	-	$s_{nb}, b_{nb} < s_b, b_b$	< 1	0.314	+0.001
Age structure	4b	2	-	$s_{nb}, b_{nb} < s_b, b_b$	> 1	0.423	+0.043
Recent breeding history, 1 age class	4d	2	-	$s_{nb}, b_{nb} < s_b, b_b$	< 1	0.324	+0.041
Recent breeding history, 6 age classes	4d	2	35	$s_{nb}, b_{nb} < s_b, b_b$	< 1	0.324	+0.064

723 **Figure captions**

724 **Figure 1.** Life cycle graphs with different types of nonbreeders and population
725 organizations, assuming a pre-breeding census. (a) System with two classes dis-
726 tinguished by breeding status (breeders, B, and nonbreeders, NB). Im is a class
727 of immature individuals that have not yet reached the age of maturity, a_m . (b)
728 System with two types of nonbreeders; inexperienced (have not yet bred) and ex-
729 perience (have bred previously). (c) Age-structured system in which probability
730 of becoming a breeder (or other parameters) change with age. (d) System with
731 senescence. After age $a_{se} - 1$, individuals have a probability, p_{se} , of becoming
732 old nonbreeders that never re-enter the breeding population. (e) System in which
733 probability of becoming a breeder (or other parameters) depends on the time an
734 individual has had a particular breeding status. (f) When age at maturity, a_m , is
735 one, offspring move directly into the breeder or nonbreeder class. When $a_m > 1$
736 there are classes of immature individuals, Im. After age $a_m - 1$, individuals move
737 into the adult B or NB class. Models in panels a-e are shown with $a_m = 2$. With
738 a post-breeding census, life cycle graphs have an additional class of newborns.

739 **Figure 2.** Population growth rate estimates from full population model (solid
740 lines) and observations of breeders only (dashed lines) in a post-breeding census
741 model. All individuals are assumed to die after age 3 (panels a, b), 4 (c, d) or 7
742 (e, f). Age at maturity is $a_m = 1$, fecundity $f_{post} = 1.5454$, and newborn survival
743 $s_o = 0.5$. This is equivalent to a fecundity of $f = 0.7727$ in the pre-breeding census
744 model (Fig. 3f) where fecundity includes survival to age 1. All other parameters
745 are set equal to those in Fig. 3f (see table S2). In panels a, c, e nonbreeder survival

746 probability is adjusted from 0.1 to 0.9. In b, d, f the transition probability b_{nb} is
747 adjusted from 0.1 to 0.9.

748 **Figure 3.** Sensitivity of the deterministic population growth rate, λ , to survival
749 probabilities (s , bars to the left of dashed lines) and probabilities of becoming
750 or remaining breeders (b , bars to the right of dashed lines). Bar colors indicate
751 breeding status; immature (im , white), breeder (b , gray), and nonbreeder (nb ,
752 black). Note that b_{am} is the probability of breeding at first maturity. Breeding
753 probability for younger immatures is zero. All systems follow the “breeding status”
754 and “age at maturity” life cycle (Fig. 1a,f) with high survival and medium age at
755 maturity (“long-lived,” panels a-c) or low survival and low age at maturity (“short-
756 lived,” d-f). Nonbreeder survival and breeding probabilities (s_{nb}, b_{nb}) are either
757 lower (panels a, d), equal (panels b, e) or higher (panels c, f) than survival and
758 breeding probabilities of breeders (s_b, b_b). Exact parameter values are in Table S2.

759 **Figure 4.** Sensitivity of the deterministic population growth rate, λ , to survival
760 probabilities (s , bars to the left of dashed lines) and probabilities of becoming
761 or remaining breeders (b , bars to the right of dashed lines). Bar colors indicate
762 breeding status; immature (im , white), breeder (b , gray), and nonbreeder (nb ,
763 black). Additional subscripts distinguish different types of nonbreeder (or breeder)
764 classes; inexperienced (in), experienced (ex), young (y), age (numeric subscripts,
765 panel b), consecutive year breeding/not breeding (numeric subscripts, panel d). (a)
766 “Breeding experience” system (Fig. 1b) where $s_{nb_in}, b_{nb_in} < s_{nb_ex}, b_{nb_ex} < s_b, b_b$;
767 (b) “Age structure” system (Fig. 1c) where survival and probability of becoming
768 (or remaining) a breeder increases and then decreases again with age and $s_{nb}, b_{nb} <$

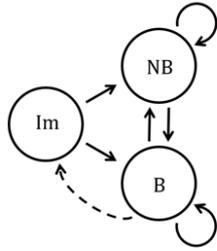

769 s_b, b_b at all ages; (c) “Senescence” system (Fig. 1d) where individuals have a 0.6
770 probability of entering the senescent age class at age 5 and above; (d) “Recent
771 breeding history” system (Fig. 1e) where the probability of remaining a breeder
772 decreases with time spent in the breeding class and individuals are very unlikely
773 to breed more than three times consecutively. Nonbreeders are slightly more likely
774 to become breeders after two (or more) time steps not breeding. Exact parameter
775 values are in Table S3.

776 **Figure 5.** Sensitivity of the deterministic population growth rate, λ , to survival
777 probabilities (s , bars to the left of dashed lines) and probabilities of becoming
778 or remaining breeders (b , bars to the right of dashed lines). Bar colors indicate
779 breeding status; immature (im , white), breeder (b , gray), and nonbreeder (nb ,
780 black). b_{am} is the probability of breeding at first maturity. All systems follow the
781 “breeding status” and “age at maturity” life cycles (Figs 1a,f) with low survival
782 and low age at maturity. Survival and breeding probabilities are set such that the
783 equilibrium ratio of nonbreeders to breeders, N_{nb}^*/N_b^* , is (a) greater than one, or
784 (b,c) equal to one. In (b,c) $b_{am} = b_{nb} = b_b = 0.5$. Nonbreeder survival (s_{nb}), is (a,
785 b) equal to breeder survival (s_b), or (c) higher than breeder survival (s_b). Exact
786 parameter values are in Table S2.

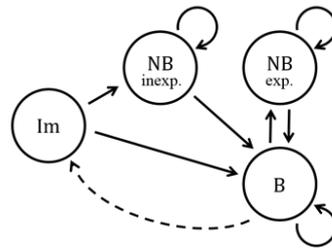

787 **Figure 6.** Sensitivity of the deterministic population growth rate, λ , to survival
788 probabilities (s , bars to the left of dashed lines) and probabilities of becoming or
789 remaining breeders (b , bars to the right of dashed lines) in systems with frequency
790 dependent effects of nonbreeders on breeder survival (panels a, c, e, g) or fecun-
791 dity (panels b, d, f, h). Bar colors indicate breeding status; immature (im , white),

792 breeder (*b*, gray), and nonbreeder (*nb*, black). Hatched bars indicate negative
793 sensitivities (i.e, an increase in the parameter decreases λ). Additional subscripts
794 distinguish among different types of nonbreeder (or breeder) classes; inexperienced
795 (*in*), experienced (*ex*), young (*y*). Systems are equivalent to those shown in Fig. 3a
796 ("Long-lived"; panels a,b), Fig. 3d ("Short-lived"; c,d), Fig. 4a ("Breeding expe-
797 rience"; e,f) and Fig. 4c ("Senescence"; g,h). λ is 0.85, 0.96, 0.90, 0.84, 0.81, 0.96,
798 0.83, 0.82 in panels a-h respectively. All systems reached equilibrium within 200
799 time steps.

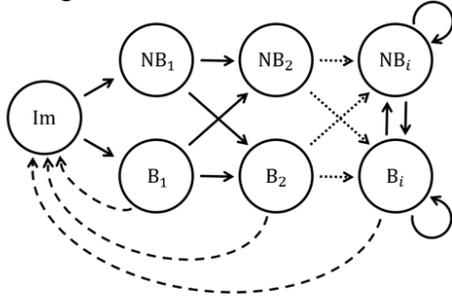

a – Breeding status

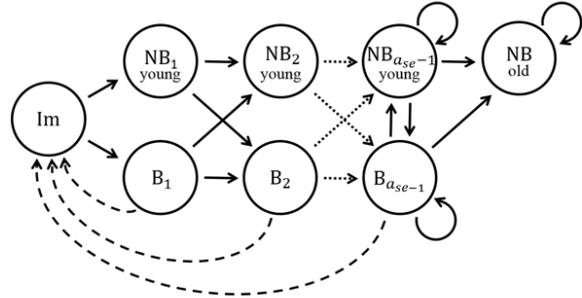

b – Breeding experience

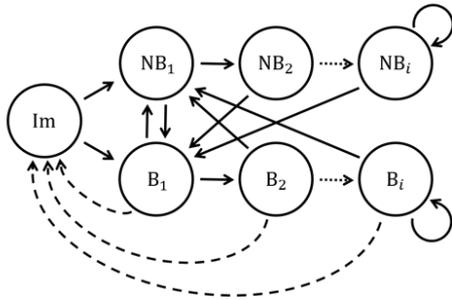

c – Age structure

d – Senescence

e – Recent breeding history

f – Age at maturity
